In young ducks *Plasmodium lophoceres* infections usually terminate fatally with low counts of both the red blood corpuscles and parasites. The parasites increase during the course of about a week to reach a peak in which the blood shows from 355 to 490 infected cells for 500 red cells. Shortly before the peak is reached the number of red cells begins to diminish rapidly to fall in the course of 48 hours to 500 000 per cmm. From 2 to 24 hours after the commencement of the fall in the red cells the diminution in the number of parasites begins. Not infrequently following the commencement of the fall in the parasite count there is a short rise in the count which does not usually reach the initial peak. In the case of the occasional duck that survives the parasites disappear from the blood while there is a rapid increase in the red cell count, which reaches normal in about a week. If infected ducks are transfused with normal duck blood in sufficient amounts to maintain the red cell count at its normal level it is found that the parasite count also remains high. The transfusion thus not only postpones the advent of the anaemia but also delays the fall in the parasite count. This result is reached only if the quantity of normal blood is adequate e.g. 5 transfusions of 5 cc. and 4 of 10 cc. in 48 hours. If the quantity is less than this the course of the infection is unaffected. Though transfusion may not save the life of the ducks its immediate effect is a marked improvement in health which is most evident in the most anaemic. It is generally supposed that phagocytosis is mainly responsible for the fall in the parasite count which occurs after the peak has been reached. The authors consider that if this were true the parasite count should not be maintained by transfusion which would not be expected to prevent phagocytosis from progressing normally. They suggest that factors other than phagocytosis may be significant in producing the decrease in the parasite count which follows the peak of the infection.

TALIAFERRO, W. H. & BLOOM, W. Inflammatory Reactions in the Skin of Normal and Immune Canaries and Monkeys after the Local Injection of Malarial Blood. *J Infect Dis.* 1945 Sept-Oct v 77 No 2, 109-38, 7 pls [25 refs]

The object of the experiments described in this paper was the study of the local reactions when small quantities of malarial blood were inoculated subcutaneously (canaries) or intracutaneously (monkeys) into normal and immune canaries and monkeys. The malarial parasites involved were *P. cathemerium* for the canaries, *P. brasilianum* for cebus and spider monkeys, and *P. knowlesi* for rhesus monkeys. Control experiments were carried out by injecting normal blood or trypan blue. Conclusive evidence was obtained that the reaction was much more marked with *P. knowlesi* than with the other parasites. Thus red cells containing large stages of *P. knowlesi* were agglutinated and localized in the skin of immune rhesus monkeys but were not agglutinated at all in normal rhesus monkeys. In addition, inflammation including phagocytosis by heterophiles* and macrophages was more marked in the skin of immune than of

*Heterophile leucocytes in man and in the above species of monkeys are the polymorphonuclear neutrophils; the granules are more acidophilic in the guinea-pig, rabbit and canary and were called pseudo-eosinophils. See MARSHALL & BLOOM, *Textbook of Histology* 1942, 4th Ed. Saunders, pp. 47 & 48.—Editor

normal rhesus monkeys. In contrast inflammation was less marked in immune canaries, cebus monkeys and spider monkeys while agglutination did not occur. It would seem that the marked reaction in immune rhesus monkeys is due to the great content of circulating antibody which allows effective amounts of this substance to leave the blood and enter the inflamed area. In both immune and non-immune monkeys and canaries skin reactions to injections of malarial blood or trypan blue proceeded more rapidly than do the reactions in the skin of rats following the injection of trypan blue as described by the MÖLLENDORFFS and MAXIMOW.

KNISELY, M. H., ELIOT, T. S. & BLOCH, E. H. *Sludged Blood in Traumatic Shock. I. Microscopic Observations of the Precipitation and Agglutination of Blood flowing through Vessels in Crushed Tissues.* *Arch Surg.* 1945 Nov-Dec v 51 No 4 220-36 1 fig [Refs in footnotes]

This paper contains a further report on the direct microscopic examination of blood and small vessels in living frogs and mammals under normal conditions and following damage by crushing and also in stage III of acute *P. knowlesi* malaria in monkeys; see also this *Bulletin* 1943 v 40 584].

Under control conditions the authors observed that circulating red cells travel free inside the vessels and do not agglutinate and that white cells do not stick to the vessel endothelium.

In stage III of *P. knowlesi* infection a thick glassy precipitate forms between and around the red cells, the precipitate forming simultaneously in about 20 minutes throughout the whole body. The precipitate binds the cells together in wads and masses (*not rouleaux*) the circulating blood coming to resemble sludge. This sludge resists its own flow through the small vessels so that stagnant anoxia develops, the affected endothelium ultimately allowing fluid to leak into the tissues with steady loss of intravascular fluid volume. Anoxia of the endothelium alone is sufficient to cause this. The red cells in *P. knowlesi* infection are not stuck to the endothelium but are apparently stuck to the phagocytes of the liver, bone marrow and spleen, which readily ingest them, so contributing towards the malarial anaemia.

The authors consider the precipitate to be fibrin or something similar to it, and devised experiments to observe the effect of the introduction of freshly formed fibrin into the circulation. For this purpose they observed the behaviour of blood cells and vessels in living animals after crushing trauma of various degrees first in the omentum and then in muscle. They found that after crushing there were in general, three regions of injury —

(a) A zone in which small vessels are thrombosed — no sludge is poured into the venous system.

(b) A sludging zone in which each venule pours out sludge into the general circulation such out pouring going on for long periods.

(c) A zone in which there is insufficient injury to cause any detectable change in the circulating blood.

The authors conclude that when they are crushed striated and smooth muscles release substances capable of diffusing in through the vessel walls and reacting with constituents of the blood flowing through the patent vessels.

[This important paper should be read in the original by those who are interested in the vascular phenomena associated with shock like conditions]

[The arguments in this paper are facile but not altogether convincing in some respects. Nevertheless it is a valuable paper the importance of which is perhaps best expressed in the words of Schwenker and Comptoir (1939 referred to by Dr Gear) the entire theory discussed here is based on only a frail foundation. However what evidence there is supports it as a possibility. Its value lies in offering a basis for further experimental work.]

TRYPANOSOMIASIS

GALLAIS P Les formes neuro-psychiques de la trypanosomiase humaine africaine (Essai d'une systématisation clinique et physiopathologique) [The Neuropsychological Forms of African Human Trypanosomiasis.] *Les Grandes Endémies Tropicales* (Onzième Année.) 1939 Paris pp 113-51

The symptoms and signs of African sleeping sickness are all well known but they have not yet been systematically grouped and the author thinks that this explains why physicians outside tropical Africa often fail to diagnose the disease. In the nervous stage there is a general family resemblance among sleeping sickness patients. The disease is a diffuse meningo-encephalitis which though it resembles syphilitic meningo-encephalitis to some extent has special features of its own. Certain regions of the central nervous system are particularly affected and this gives it a clinical picture very different from that of general paralysis.

The fundamental neuro-psychical syndrome results from involvement of the region around the third ventricle—the hypothalamic region with the nuclei of the autonomous nervous system which are situated there. The symptoms may be classified as tropho-vegetative, psychic, motor and sensory. These are described in considerable detail with notes of illustrative cases.

The author discusses the pathological lesions of the central nervous system they are associated with the capillaries and the Virchow Robin perivascular sheaths. He concludes that in trypanosomiasis there is a diffuse involvement of the walls of the cavities—the pia-arachnoid membrane with its prolongations and the ventricular ependyma with the choroid plexuses i.e. the parts where the cerebrospinal fluid is formed, circulates and is reabsorbed.

GROUPÉ V. & DONOVICK R. Studies on Toxicity Complement-Fixing and Immunogenic Activity of Typhus-Infected Yolk Sacs. *Proc Soc Exper Biol & Med* 1945 Dec 1 60 No 3 349-51 [10 refs.]

In the conditions described in the paper it was found that suspensions of yolk sacs infected with the Breinl strain of epidemic-typhus rickettsiae increased in toxicity in relation to the number of days of survival of the chick embryos from which the suspensions were prepared. Vaccines prepared from the suspensions showed a corresponding rise in antigenicity in relation to the survival period and the complement fixing activity of the antigens contained in the vaccines increased in the same way.

The toxicity experiments were carried out with untreated yolk-sac suspensions prepared from embryos still living on the 5th 6th 7th and 8th days respectively after inoculation and it was found that certain dilutions of the 5th-day suspensions failed to kill any of the test mice whereas corresponding dilutions of 8th-day suspensions killed all the test mice. The complement fixing titres of these suspensions showed a corresponding degree of variation being lowest in 5th-day suspensions and highest in 8th-day suspensions.

Vaccines were prepared from yolk sacs of embryos that died 5-7 days after inoculation and from yolk sacs of embryos still surviving after 7 days the results of tests of these vaccines are illustrated by the following examples —

	Vaccines prepared from embryos			
	D-5 ⁽¹⁾	D-6	D-7	L-7 ⁽²⁾
Number of yolk sacs	90	102	146	65
Richness in rickettsiae	±	+	++	+++±
Complement fixation at titre 1-64	0	2+	3+	4+
Percentage of mice protected by 0.2 ml. of vaccine	21.4	62.9	No test	85.7

(1) D-5 means dead after 5 days. (2) L-7 means still alive after 7 days.

The toxic and complement-fixing substances are not identical the former are destroyed by formal and ether which do not affect the latter yet both are more active in yolk-sac suspensions of long-surviving than of short-surviving embryos.

DONOVICK R. FARRELL Mary & SMITH Florence. The Antibody Response of Guinea Pigs to Epidemic Typhus Vaccines of various Antigenicities. *J Bacteriology* 1945 Sept 1 50 No 3 241-7 3 figs

In this investigation 48 lots each consisting of 12-20 guineapigs were vaccinated with two doses of one of 43 different batches of epidemic typhus

[July 1946]

The authors found that a number of phenanthridine compounds exhibit definite therapeutic activity against these infections in mice. In order to examine the matter properly it was first necessary to determine accurately the course of untreated *T. cruzi* mouse infections, since these tend to be somewhat variable. The authors therefore passaged their strain, subcutaneously as soon as parasites became numerous in the blood since previous work with *T. congolense* had shown the advantages of using such an "acme" strain [BROWNING and CALVER, this Bulletin 1945 v. 42, 259. CALVER, *ibid* 704]. In more than 140 such passages the trypanosomes became abundant in the blood in all but one case and 82 per cent. of the mice died of the infection within 30 days, mostly between the thirteenth and nineteenth days. The remaining 18 per cent. showed a chronic course, surviving indefinitely, and parasites were scanty or absent for prolonged periods. Accordingly in assessing the effect of treatment it was necessary to allow for spontaneous suppression of the infection in a proportion equivalent to that shown by untreated controls.

Treatment consisted of one subcutaneous injection given as soon as scanty parasites appeared in the blood, and mice were reckoned as cured if trypanosomes disappeared from the blood permanently, either at once or after becoming numerous for not more than two or three days. The question of possible influence on the intracellular stage of the parasite was not examined. Activity similar to that exhibited by Bayer 7802 (4c) was shown by 3-carbethoxyvrammo-9-*p*-carbethoxyvrammophenyl 10-methylphenanthridinium chloride (S 1544) and the corresponding much more soluble, methanesulphonate (S 1577). The degree of activity, although the best yet encountered, is still not of a very high order.

It is interesting that the presence of a phenyl ring in the 9 position is not essential for activity as was shown by a significant therapeutic response to 2,7-dicarbethoxyvrammo-9-10-dimethylphenanthridinium methanesulphonate (S 1582).

Immunity phenomena were believed to play a considerable part in the therapeutic effect since cured animals and those showing suppression of infection failed to develop an obvious infection when reinoculated, even many months later. Nevertheless, unlike the case with *T. congolense* [BROWNING and CALVER, *loc cit*] treatment is more successful at an early stage of infection than later when parasites are numerous in the blood.

The above phenanthridinium compounds which influence *T. cruzi* do not affect *T. brucei* or *T. congolense* infections, except in high doses. E. V. LOHRIS.

LEISHMANIASIS.

MORALES A. L. Nueva aportaciones a la quimioterapia del Kala Azar infantil por el Solusibosol concentrado. "Treatment of Infantile Kala Azar with Concentrated Solusibosol." *Rev. Sanidad e Hig. Pública*. 1945 Aug., v. 19, no. 8, 529-35.

The paper reports the successful treatment of ten cases of infantile kala azar in children up to five years of age, with concentrated solusibosol (sodium antimony gluconate). The drug was given intramuscularly in ten or eleven daily doses. In three cases the total quantity was 1 cc. per kilo. of body weight in seven it was 1.5 cc. Better and more rapid results were obtained with the higher dosage, which was well tolerated by all the children. Treatment

commenced with an initial dose of 0.2 to 0.5 cc. according to the age and weight of the child this was increased till a maximum daily dose was reached which varied from 0.7 to 2 cc. Thus in a child 4 years old weighing 14.5 kilo the course consisted of 0.5 1.0 1.5 followed by nine doses of 2.0 cc.

DONOVICK R. FARRELL Mary & SMITH Florence. The Antibody Response of Guinea Pigs to Epidemic Typhus Vaccines of various Antigenicities. *J. Bacteriology* 1945 Sept v 50 No 3 241-7 3 figs.

In this investigation 48 lots, each consisting of 12-20 guinea pigs, were vaccinated with two doses of one of 43 different batches of epidemic typhus

[July 1948]

vaccine, the sera of each lot of animals were collected and pooled 14 days after the administration of the second dose of vaccine. The antigenic titres of the vaccines ranged from 1-8 to 1-32. The antibody titres of the sera were tested by complement-fixation and mouse-neutralizing tests, and were found to correspond broadly with each other and also with the antigenic titres of the vaccines employed in immunizing the animals.

The authors conclude that a direct determination of the antigenic titre of the vaccine by the complement-fixation test appears to give an accurate measure of its protective value for guinea-pigs.

The general trend of the findings can be seen from the following analysis of the tables contained in the paper —

Antibody Titres of Sera of Pools of 12-20 Vaccinated Guinea-pigs		Complement Fixation Titres			Mouse-Neutralizing Titres			
		Range	1-8 or less	1-16 or more	Range	1-8 or less	1-16 or more	1-32 or more
1-8	13	1-4 to 1-32	5	6	1-8 to 1-32	4	6	8
1-16	19	1-4 to 1-128	6	8	1-8 to 1-128	6	5	8
1-32	18	1-8 to 1-256	1	4	1-8 to 1-64	2	4	10

Surprisingly great variations were observed in the antibody titres of different lots of animals immunized by the same vaccines in some cases the complement fixation titres ranged from 1-8 to 1-32, and in one case the mouse-neutralizing titre of pooled serum from one lot of 20 guinea-pigs was 1-128 whereas the titre of another lot of 20 that had received the same vaccine was 1-8. Even allowing for great variations in the susceptibility of individual animals it would not be expected that two lots of pooled serum, each obtained from 20 guinea-pigs selected at random and treated in the same way should show such differences in their responses. The author feels compelled to suggest that it would be necessary to include 100 or more animals in each lot in order to obtain approximately similar responses with the pooled sera. John W. D. McGraw

DR. ALKISS E. Epidemia di tifo esantematico in Grecia [An Epidemic of Typhus in Greece.] *Giorn. di Batteriol. e Immunol.* 1943 Aug v 31 No 2 89-98 English summary (4 lines)

YEOMANS, A. SNYDER, J. C. MURRAY, E. S. ECKE, R. S. & ZARAFONETIS, C. J. D. Anaemia in Typhus Fever. *Ann Intern Med* 1945 Nov v 23 No 5 711-53 10 charts (38 refs)

The authors comment on the scantiness of the information available on the subject of anaemia in the literature of typhus fever and on the greatly conflicting views expressed by the few German and French workers who have studied the condition.

In the present investigation, 64 Egyptian patients were studied in the U.S.A. Typhus-Communion Ward of the Cairo Fever Hospital in 1943-44. It was soon found that the severest cases were in a condition of anaemia which was regarded as existing when the non-protein nitrogen of the blood was

45 mgm or over per 100 cc. Some of the patients affected were in a uraemic condition some had pronounced hypotension and some were severely dehydrated

The incidence and degree of azotaemia among the patients is shown in the table which has been compiled from data contained in the paper —

Severity of attack	No of patients	No. having azotaemia	Maximum Non Protein Nitrogen in Blood of Azotaemic Patients (mgm. per 100 cc)	
			Average	Range
Very mild	2	0	—	—
Moderate	14	4	58	47-74
Severe	26	9	69	58-117
Very Severe	7	5	92	72-162
Fatal	15	15	120	75-200

The average age of the 64 patients was 28 years of the 15 who died it was 33 years. There were no deaths among the patients who remained free from the condition. The average daily blood pressure was not lowered in the affected patients but in many cases there was a sudden fall in the systolic pressure at the time of onset of the condition there was often also a diminution in the urinary output at this time azotaemia was rarely seen so long as the output remained above 2 000 cc. The time of onset was usually during the second week but in a few cases it was before the 8th day. The specific gravity of the urine tended to be low considering the reduction in the output. Dehydration often associated with insufficient fluid intake was regarded as an important contributory factor.

Albuminuria was present in all the cases red and white cells were often found in the urinary sediment cell casts were rarely seen but granular casts were often present. After recovery it was exceptional to find evidence of renal damage this occurred in two cases, but the kidneys might have been affected before the attack.

Detailed reports illustrated by charts are given of ten cases of which six were fatal. The investigation was exceptionally thorough and the charts form a graphic record of the chief features of each case.

The cause of the condition is discussed at some length. In view of the above reference to deficient fluid intake and of the statement that inadequate intake of total calories is an important contributory factor it is surprising to learn that the diet of most of the patients consisted of water sweetened fruit juices and 600 to 1,000 cc. of milk daily. [This diet which is inadequate in proteins as well as in calories (as the authors themselves state) would not be expected to support the nutrition of the renal cells the cardiac muscle, and the other tissues, already damaged by the infection. From the charts it appears that the daily fluid intake sometimes fell as low as two pints or even less. These circumstances combined with the high virulence of the infection and the relatively low standard of nutrition of the patients before the illness, may account for the exceptional degree of frequency of the condition in the present series of cases. Other observers have recorded very different findings for example, SCHÄFER (this *Bulletin* 1946 v 43 210) found no reading higher than 63 mgm. per 100 cc. during the second week among seven severe cases and in the two of these that were fatal the readings were 21 and 35 mgm respectively.]

John W D Morgan

[July 1946]

CRAUFORD-BENSON H J & MACLEOD J A.L.B.S. the Original British Army
Louse Powder J Hygiene 1946 Jan., v 44 No 4 294-306 3 figs.
[11 refs.]

This paper describes the work which led to the development of A.L.63 which was the official British Army louse powder from 1940 until the introduction of DDT in 1944. It was the only louse powder used by the British troops and the civilians employed by the British Army during the Naples typhus epidemic of 1943-44. Except for two cases, where negligence was shown, there were no cases of typhus among the troops or among the 25,000 civilian employees treated at fortnightly intervals.

The problem was to develop a preparation for use by the individual which would (a) kill lice already present (b) prevent infestation or re-infestation. The value of a preparation was established by laboratory scale tests, in which the lice were dusted and exposed to treated flannellette in boiling silk bottomed boxes worn on the leg during the daytime and by practical tests with naturally lousy people in a specially established clinic in the East End of London. In the latter experiments the underclothes or specially provided shirts worn next to the skin were dusted.

All the dusts were made up with a kaelin base. The substances tested included among others pyrethrum, derris, naphthalene, high boiling tar acids and creosote used alone and in various combinations. It was soon found that different results were obtained in the laboratory and field tests, and that, in general, higher concentrations of insecticide were necessary in the practical work.

Naphthalene killed the body lice most quickly but failed to give lasting protection. Derris and pyrethrum were toxic to lice, but either alone or mixed they were inferior to other insecticidal combinations. It was found that mixtures of high boiling tar acids and derris showed an activation effect and such a mixture was more effective than either ingredient alone. Thus activated derris mixture was slow in action, but gave better lasting protection than other mixtures. By combining the rapid action of naphthalene with the lasting effect of derris activated with high boiling tar acids, formula A.L.63 was obtained, i.e. high boiling tar acids, 2 per cent. derris root 14.3 per cent., giving 1 per cent. rotenone. Naphthalene 50.0 per cent. china clay 33.7 per cent. A.L.63 gave a 98 per cent. kill of lice present on treated garments at the time of application and protection from reinfestation for five days. When the subject was exposed in an infested environment it was found that retreatment at eight-day intervals gave effective protection. Applied as a prophylactic to clean garment A.L.63 remained effective for seven to eight days and gave partial protection up to 16 days.

CRAUFORD-BENSON H J Naples Typhus Epidemic, 1943-3 (as seen by an
Entomologist Brit Med J 1946 Apr 13 578-80 1 graph.)

The epidemic of typhus in Naples during the winter of 1942-43 reached its maximum (300 cases a week) early in January and then the number of cases fell rapidly. Previous experience would have led to the expectation that the number of cases would have gone on increasing to much higher levels during the early months of 1943 and there is little doubt that a dramatic result was obtained by the control measures described in this paper. These consisted of the mechanical application of louse powders to fully clothed individuals, a method which though not immediately rendering them louse-free enabled enormous numbers to be dealt with (2,759,000 individual applications up to April 1943). It also made those treated relatively "louse-proof". Although

DDT is usually credited with the responsibility for the success achieved, it is here shown that the initial fall in incidence was mainly caused by the use of MYL the American powder containing pyrethrum and that the 20 000 civilian employees of the army were well protected by fortnightly dusting with the original powder AL63 which contains derris and naphthalene. The later control was by means of DDT

Kenneth Mellanby

WHEELER C M Control of Typhus in Italy 1943-1944 by Use of DDT *Amer J Pub Health* 1946 Feb 36 No 2 119-29

The author a member of the U.S.A. Typhus Commission describes the organization by which louse borne typhus was promptly brought under control in Naples and Southern Italy in 1943-44. The remarkable success which was achieved in Naples ceases to be a matter of surprise to anyone who reads this report.

Preventive measures were started under the direction of the medical staffs of the Allied Forces and later were controlled by the U.S.A. Typhus Commission. As is shown by the title of the paper chief reliance was placed on the use of DDT. This was used in the form of a 10 per cent dusting powder of which 1-1½ oz. was applied by hand-duster or by power-dusters to each person. The powder was blown between the skin and the inner layer of clothing and between the outer layers of clothing bedding and spare clothing in houses were also dusted when necessary.

The large team of workers employed was divided into a number of sections (1) Case Finding Section (2) Contact Delousing Section (3) Case Contact Service (4) Special Services (5) Ricovero (Air Raid Shelter) Service (6) Mass-Delousing Section (7) Immunization Section (8) Flying Squadron Section later (9) a Refugee Section was established to deal with groups of refugees from Yugoslavia and other countries. The Flying Squadron Section attended to outbreaks reported from places outside Naples in southern Italy.

No adequate summary can be given of the work of the organization especially as this was modified from time to time according to the needs of the situation. In a table it is shown that in Naples more than two and a half million dusting operations were performed and in other places there were more than 600 000. The number of cases of typhus reported in Naples was 1 404 elsewhere in southern Italy there were 510 cases.

Within a month of the institution of control measures in Naples on December 15th 1943 a sharp decline in the number of cases set in and by February 20th 1944 the epidemic appeared to have been definitely broken.

The Mass-Delousing Section was organized for the primary purpose of delousing the entire civilian population of Naples. It was planned on the basis of 50 stations equipped to dust as many as 100 000 persons daily. By February 8th 40 such stations were working with a combined staff of 439 persons. The whole operation was a triumphant success not only for DDT but also for the persons who planned and conducted the campaign.

John W D Megaw

BEALL J C Permanent Program for Typhus Fever Control in Memphis, Tennessee. *Amer J Pub Health* 1946 Feb 36 No 2 161-8.

Readers outside the U.S.A. will probably be surprised to find that the Programme for Typhus-Fever Control described in this paper is purely one of rat control. The disease referred to is of course the one commonly called murine or endemic typhus not louse borne typhus.

[July 1948]

Tropical Diseases Bulletin

In Memphis City a permanent organization has been set up with a view to preventing the disease from establishing itself and apparently no cases had been reported till some months after the commencement of the planning of the campaign when an outbreak of six cases occurred in a feed mill during August and September 1943.

In the month of November of the same year the City Commissioners adopted an ordinance by which owners of all business premises were made responsible for keeping their buildings free from rats. The official organization included the purchase of initial equipment costing \$8,000 but it was planned on a self supporting basis and all owners were compelled to pay for the cost of the necessary operations whether these were carried out by themselves or by the special section of the health staff. The personnel of the organization consisted of a public-health engineer, three field foremen, a sanitarian, and 22 negro labourers of whom 12 were assigned to rat proofing, 8 to rat trapping and poisoning, and 2 to special work. The equipment included one motor car, three 1½-ton trucks and one ½-ton truck.

Up to the time of writing 299 business establishments had been dealt with at an average cost of \$47.76 each. Apart from the compulsory powers provided by the ordinance efforts were made to secure the willing co-operation of owners by a publicity campaign.

The residential area of the City has not yet come within the scope of the campaign, but plans are being made for the inclusion of these at a later date and for the compulsory inclusion of rat proofing of all new buildings.

The description of the organization will be found interesting by all concerned with rat control though so high a standard of achievement would be unattainable in most of the places where the rat is a menace to public health.

John W. D. Meigs

JOHNSON D. H. & WHARTON G. W. Tsutsugamushi, Disease Epidemiology and Methods of Survey and Control. *U.S. New Med Bull* 1948 Mar 48 No 3 459-72, 1 fig

This paper contains a useful summary of what is known of the epidemiology and prevention of tsutsugamushi disease. The word chiggers is defined as "the larvae of mites of the family trombiculidae" of which about 150 species are known including at least 100 in the regions in which the disease occurs.

A description is given of the characteristics by which these larvae can be distinguished from other minute arthropods. Rickettsiae are believed to be introduced into the body of the host with saliva, which is injected by the larvae and which dissolves the tissues, so preparing them for ingestion. The larva after its one and only meal, drops off and buries itself in the upper layers of the soil in the nymphal and adult stages. The mite is non-parasitic feeding on any object that disturbs their habitat. They are hatched out from the soil in the nymphal and adult stages. Infection is believed to be transmitted through successive generations of mites which may therefore be the real reservoirs of infection. But even if the animal hosts should be found to play no direct part in the transmission cycle they would still be essential for the maintenance of the mite population. Many vertebrates are often bitten and these when they migrate are likely to convey living mites to distant places.

Many rats make their nests in places suitable as habitats for the mites. The infected mites to be strictly localized are usually moist, but well-drained, and are covered with herbaceous and scrubby vegetation. Such areas are specially likely to be selected as sites for camps. Coconut and other food

trees or plants attract rats. Water-logged or dry soil and dense jungle are seldom infested by mites

Directions are given for the trapping of rats and for the examination of these and the other vertebrate hosts for the detection of mites. Methods of protecting investigators from infection include the immediate immersion of trapped rats in 80 per cent alcohol ideally or alternatively the temporary use of tight lidded canisters the wearing of impregnated clothing frequent application to the hands and wrists of dimethyl phthalate and the placing of the dead bodies of animals under examination on large trays smeared with dimethyl phthalate

White porcelain cups were found suitable for collecting larvae the cups were placed on the ground in contact with the surface litter for one to five minutes and then examined.

If larvae are found on small mammals the presence of infection should be suspected abundant larvae on birds and reptiles are likely to be pest jiggers [larvae which cause scrub itch] Identification of species is a matter for experts.

Soil can be disinfested by DDT five to ten pounds of a 10 per cent powder is enough for each acre Dimethyl phthalate is used for personal protection and also for spraying the floors of tents and huts when the slower action of DDT might not be adequate Instructions are given for the impregnation of clothing and blankets with dimethyl phthalate which remains effective for two weeks in the absence of repeated wetting by rain. Untreated shorts should be worn under the impregnated outer garments to avoid irritation of the genitalia. For the protection of one person two ounces of dimethyl phthalate can be applied by the smear method in which a few drops at a time are spread on the palms of the hands and rubbed on the socks and clothing by repeated applications till the whole surface has been uniformly treated

The exposed skin is also smeared lightly avoiding the lips and eyes.

Dibutyl phthalate used by the smear method is preferred by the Australian Army its effect is slower but is said to be more persistent

Rat control by trapping and poisoning is recommended [though in view of the authors own account of the life-history of the mites the destruction of rats would not be expected to have an early effect in reducing the number of infected larvae it might even in certain conditions increase the risk to human beings by depriving the larvae of their usual hosts.]

The vegetation of risky camp sites should be cut and removed the stubble should be sprayed with Diesel oil or kerosene and burned or it may be dealt with by a flame thrower

CLANCY C. F & WOLFE, D. M. A Rapid Staining Method for *Rickettsia orientalis* Science 1945 Nov 9 483

The following method of staining *Rickettsia orientalis* in smears from infected yolk sac membrane or other tissues gives good results and is quicker than that of SYVERTON and THOMAS [thus Bulletin 1945 v 42 879] The smears are dried in air and fixed by heat xylol is poured on drained off, and the slide is again dried in air It is then immersed for 5 minutes in a mixture of methylene blue and basic fuchsin—each 1 5 000 in distilled water—washed in tap water and dried. The dilute stain is best freshly prepared as required e.g. daily from stock 1 per cent solution of the two dyes.

J F Corson

O'CONNOR J. L. Hirst's Haemagglutination Phenomenon exhibited by *Rickettsia orientalis* (Syn. *Tsutsugamushi*). *Med J Australia*. 1945 Dec 22, v 2, No. 25 458-60

Cultures of *Rickettsia orientalis* grown on the chorio-allantoic membrane of duck embryos caused agglutination of suspensions of red blood cells prepared from fowls, but positive results were obtained in only two of eight suspensions made from different fowls.

HIRST (Science 1941 July 4 22) (see also *Bulletin of Hygiene* 1942, v 17 698) described the agglutination of red cells of fowls by influenza virus, and CLARK and NAGLER (*Bulletin of Hygiene* 1944 v 19 184) found that the same phenomenon occurred with vaccinia virus, but only in about half of the red-cell suspensions that were tested.

In further experiments the author found that the serum of a patient convalescent from scrub typhus contained antibodies which inhibited the agglutination and that embryonic duck erythrocytes adsorbed most of the infecting agent from infected allantoic fluid. No agglutination occurred in any of six samples of red-cell suspensions made from one-day-old chicks. One sample each of human, sheep and guinea-pig cell suspensions also gave negative results. A description is given of the technical methods employed.

John W D Megaw

DE BURGH P. The Use of a Polysaccharide of *Bacillus proteus* OXK in the Diagnosis of Scrub Typhus. *Med J Australia* 1946 Jan. 19 v 1 No 3 81-3

This study was undertaken to find whether *Proteus* OXK contained a polysaccharide-like substance corresponding to the one extracted by CASTAÑEDA and ZIA (1933) from *Pr* O\19 and found by them to be a minor antigen common to *Pr* O\19 and *Rickettsia prowazekii*. The author extracted a polysaccharide from cultures of *Pr* O\19 by trichloroacetic acid, after the method of BORIS (1933) and with a solution of this he sensitized colloidal particles prepared according to the technique of LOEB (1922). Details of the methods are given. Sera of two patients convalescent from scrub typhus agglutinated the sensitized particles at the same titres (1-320 and 1-640) as were observed when *Pr* O\19 suspensions were used. The reaction is rapid, taking only 15 minutes. It appears to be more specific than the standard test because among eight samples of normal sera there were seven which gave positive reactions at a titre of 1-40 with *Pr* O\19 suspensions containing both the major and minor antigens whereas there were no positives with the sensitized particles, containing only the minor antigen.

The suspensions of sensitized particles had a life of about one week in the ice-box. It is suggested that in certain conditions the advantages of the reaction may outweigh the drawback involved in the laborious method of preparation, and that other antigens such as *Pr* O\19 may be used in the same way.

The polysaccharide was also used with success in a precipitin test but this was less satisfactory than the agglutination test.

TRAVASSOS J & VALLEJO-FRERE A. Criação artificial de *Imithomya cayenensis* para o preparo da vacina contra a febre maculosa. Artificial Breeding of *Imithomya cayenensis* for the Preparation of Vaccine against São Paulo Spotted Fever. *Mem Inst Butantan*, 1944-1945 v 18 145-235 32 figs. (3 coloured pls) (38 refs.)

This interesting paper is really a monograph dealing with the preparation from ticks of a vaccine against the highly virulent São Paulo type of tick borne typhus. It consists of 90 large pages of text illustrated by 32 figures and three good coloured plates.

The disease is an important public health problem in the rural areas of the State of São Paulo where since the discovery of the disease in 1929 hundreds of deaths have occurred in widely distributed areas and in some places the disease interferes with the extension of agriculture.

Tick control was regarded as impracticable so that an organization was established at the Butantan Institute in São Paulo for the production of a vaccine by the method worked out by SPENCER and PARKER for the closely related disease Rocky Mountain spotted fever [see this *Bulletin* 1926 v. 23 361].

The pioneer worker on the vaccine in Brazil MONTEIRO and his assistant Edison DILLIS died of accidental infections acquired in the laboratory.

The chief vector *Amblyomma cajennense* is the most abundant tick in the State and is also the easiest to rear in the laboratory its life-history and identification are clearly described. Details are given of (1) the method of breeding the tick on a large scale (2) feeding the larvae on infected rabbits (3) maintaining the infected ticks till they reach maturity (4) the preparation and testing of the vaccine and (5) the protection of workers from accidental infection. All these procedures are fully described, with the help of numerous photographic and other illustrations which in themselves will be found very useful by those who undertake experimental work on ticks.

Little information is given about the output and distribution of the vaccine and the authors admit that evidence of its efficiency in the field is very difficult to obtain. It is regarded as likely that vaccination and six monthly revaccination give the same degree of protection as has been obtained by Spencer and Parker in Rocky Mountain spotted fever. The complete absence of laboratory accidents since the unfortunate fatalities mentioned above is regarded as significant in view of the great risk of laboratory infection despite the elaborate precautions that have been taken.

YELLOW FEVER.

ANTUNES W. & CASTRO A. Zona endêmica da febre amarela no Brasil. [Endemic Yellow Fever Area in Brazil.] *Bol. Oficina Sanitaria Panamericana* 1945 Nov. v. 24 No. 11 972-9. 3 maps & 2 graphs. English summary.

The endemic yellow fever area of Brazil based on experience of the last five years includes (a) all territory to the north of a line from the city of Brasília Acre Territory to Gurupá in Pará and thence along the Gurupá river to the Atlantic coast (b) the districts of Ilhéus and Itabuna at the east coast between the Contas and Pardo rivers. From the former area certain localities are excluded, viz Taracá Feijó Sena Madureira Amapari Brasília e Rio Branco in Acre Territory Porto Velho in Guaporé Territory Benjamin Constant Tabatinga, São Paulo de Olivença Fonte Boa Tefé Coari Codajaz Manaus Borba Itacatiara Manicoré Parintins and Humaitá in the State of Amazonas Obidos Santarém Monte Alegre Gurupá Currahinho and Belém in the State of Pará.

The demarcation plan of UNRRA [this *Bulletin* 1946 v. 43 124] does not distinguish between endemic and epidemic areas it includes a far larger area and would require periodical revision of the endemic areas to exclude quiescent epidemic areas.

J. F. Corson

[July 1946]

Tropical Diseases Bulletin.

GAST G. A. & BATES, M. La distribución estacional de fiebre amarilla humana y del mosquito *Haemagogus* en la intendencia del Meta (Colombia). [The Seasonal Distribution of Yellow Fever and of *Haemagogus* in Part of Colombia.] *Rev. Facul. de Med. Bogotá*. 1945, Oct. v 14 No. 4 243-53 1 graph. English summary

"Field studies confirmed by laboratory experimentation, indicate that the mosquito *Haemagogus* *reppinensis* is the chief vector of yellow fever in eastern Colombia. The object of the present article is to compare the seasonal variation in abundance of this mosquito with the seasonal distribution of human yellow fever in the region of Villavieja. The data for human yellow fever are based on the results of the examination of liver specimens obtained by the "Viscerotomy" Service over a period of 11 years. The data for mosquitoes are based on three years of standardized captures in a series of forest stations near Villavieja.

The climate of Villavieja is relatively uniform through the year except for a dry season extending from December through March when rains are comparatively infrequent. Human yellow fever fatalities reach a minimum at the end of the dry season (March) and do not show a significant increase until the second month of rains (June) reaching a peak in November and December. *Haemagogus* mosquitoes become relatively scarce during the dry season, but the population increases rapidly after the onset of the rains reaching a peak in June showing a slow but steady decline for the rest of the year except for a slight increase in November. It seems likely that the scarcity of yellow fever in the dry season is dependent on the low population level of *haemagogus* mosquitoes and the post-dry season increase in yellow fever remains a month behind the increase in mosquitoes. Human yellow fever remains at a high level through the rest of the rainy season, even though the mosquito population is declining and the peak of human yellow fever in November and December corresponds to only a slight rise in the mosquito population. It seems likely that the high incidence of yellow fever at this time is related to the habits of the local human population. It is customary to fell large areas of forest at this time with the object of burning the land in January and February leaving it ready for planting with the forest in November and December than at any other time of year."

LAEMCKERT H. W. Jr. Studies on Susceptibility of Marsupials to Different Strains of Yellow Fever Virus. *Amer. J. Trop. Med.* 1946 Jan. v 26 No. 1 33-46. [10 refs.]

The susceptibility of marsupials to infection with yellow fever virus was investigated by BOGGER *et al.* [this Bulletin 1941 v 38 434] and BATES (*ibid.* 1944 v 41 749) in the present paper additional experiments with various strains of yellow fever virus and several species of marsupials are recorded. Altogether 335 marsupials belonging to seven species were tested. They were caught in various parts of Brazil, all except two of which were areas in which yellow fever was either epidemic at the time or had been reported previously. The animals were of various ages from newborn to adult, but most were young. The animals were maintained satisfactorily under laboratory conditions. They were mostly inoculated subcutaneously but other routes were used in some cases for comparison. The seven strains of yellow fever virus were J.Z. (isolated in S. America in 1937), O.C. (S. America 1940), M.D. J.A. & Martinez (S. American jungle strains), Anibi (Africa) and the French neuro-tropic strain (Africa). The J.Z. and O.C. strains which had been isolated and maintained in *rhesus* monkeys were mostly used.

The viruses were titrated by intracerebral inoculation of mice and in the tests on marsupials small doses were inoculated as a rule. To test for circulating virus blood was taken from the heart on successive days and the serum inoculated intracerebrally into mice in the cases of *Didelphis* and *Metachirops* the serum was diluted as it is toxic for mice. After 30 days the surviving marsupials were bled to test for specific antibodies: no immune antibodies had been found before the inoculation of yellow fever virus.

The results of the tests are shown in seven tables from which and from the text the following details have been abstracted —

Species	Common name	No	Circulating virus present in	Immune bodies developed in*
<i>Didelphis marsupialis</i>	Common opossum	162	7	13/108
<i>D. paraguayensis</i>	White-eared common opossum	8	1	2/8
<i>Metachirops opossum</i>	Grey masked opossum	68	15	11/41
<i>M. nudicaudatus</i>	Brown-masked opossum	44	26	25/38
<i>Caluromys philander</i>	Woolly opossum	12	11	8/9
<i>Marmosa cinerea</i>	Murine opossum	11	5	2/3
<i>M. incana</i>	Murine opossum	30	23	9/15

*The proportion of survivors which developed specific antibodies.

The author concluded that *D. marsupialis*, *D. paraguayensis* and *M. opossum* were resistant to the strains used since only a few showed circulating virus and, in general the immunity response was poor. South American opossums are placental animals and the author thinks it unlikely that the newborn animals (in the pouch) acquired passive immunity from the milk of the mothers. The results in general were similar to those of Bugher *et al.* and Bates but the former authors considered these species to be susceptible. Bates regarded *M. opossum* as resistant. *M. nudicaudatus*, *C. philander*, *M. cinerea* and *M. incana* were susceptible. It is interesting that *C. philander* was susceptible to O.C. and Asibi strains but not to J.Z. strain showing that certain animal species may be resistant to one strain and fully susceptible to another strain indistinguishable immunologically from the first. This suggests that there may be still other yellow fever strains to which certain species of marsupials are more susceptible.

J. F. Corson

DENGUE AND ALLIED FEVERS

JOHNSON J. A. Jr MARTIN W. B. & BRESLOW L. Dengue-like Fever on Okinawa. *Bull. U.S. Army Med. Dept.* 1946 Mar v 5 No 3 306-11 3 charts.

A short fever in regard to which the authors state that the diagnosis of dengue seems justified, made its appearance about the 7th April 1945 among the U.S.A. troops in Okinawa Island [26°N lat.] The incidence increased gradually reaching its peak in the middle of July and then fell rapidly to zero about the middle of August. The rapid decline was associated with the establishment of mosquito control which is said to have become good by the middle of July.

Tropical Diseases Bulletin

In April and May the most abundant mosquito was *Culex quinquefasciatus* [C. fatigans]. *Aedes albopictus* was rare and only occasional specimens of *Aedes aegypti* were found. In June and July *A. albopictus* could readily be found, but *C. quinquefasciatus* was still the most prevalent mosquito, no further mention is made of *A. aegypti*. The epidemiological evidence was therefore somewhat against the diagnosis of "true dengue" but *A. albopictus* despite its low density was thought to merit consideration as the possible vector.

The clinical aspects of the disease were regarded as differing from those of dengue in the relative infrequency of a secondary rise of temperature the short average duration of the fever (3-4 days in a field hospital and 4-2 days in a clearing company) and the absence of a rash. In all other respects the disease conformed very closely to the generally accepted picture of dengue. In the field hospital, the percentage incidence of the chief symptoms and signs was as follows: Headache 83, chill or chilliness 92.5, orbital aches 100, backache 97.5, joint ache 100, adenopathy 85, conjunctivitis 95, and leucopenia 58.5. A definite reduction in the number of the polymorphonuclear leucocytes was observed by the 3rd or 4th day when there was a relative though not an absolute lymphocytosis.

The maximum incidence of the disease in one infantry division as shown in chart was at the rate of 275 per 1,000 per annum. Specimens of blood an serum have been submitted for virus studies.

[No reference is made to the occurrence of sandflies so that presumably these were not in evidence. The clinical features are more suggestive of sandfly fever than of dengue.]

John W. D. McGraw

HUBER, W. Phlebotomen und Pappatacheber in Nordkaukasien. (Referat ueber Arbeiten russischer Autoren u. eigene epidemiologische Beobachtungen.) [Sandflies and Sandfly Fever in North Caucasia.] *Deut. Tropenmed. Ztschr.* 1944 Apr-May v 48, nos. 7/10 182-92. [22 refs.]

This paper consists almost entirely of a review of recent work by Russian observers on sandfly fever in the region north of the Caucasus Mountains, between the Sea of Azov and the Caspian Sea, where the author had personal experience of the disease in the summer of 1942. He had already seen cases of fever clinically indistinguishable from sandfly fever in the Don-Donets region, situated further north where sandflies are not known to occur so that the question arose whether the virus of sandfly fever was being transmitted by insects other than the sandfly or whether the disease was caused by a different agency.

It was not till 1927 that sandflies, including *Phlebotomus papatasi* were found to occur in Northern Caucasia indeed so recently as 1934 an outbreak whose clinical features were those of sandfly fever was regarded as one of "mosquito disease". In 1935 widespread outbreaks occurred in the region and were attributed to virus transmitted by *P. papatasi*.

The disease was closely studied, especially by MOSCHKOWSKY and his colleagues who in 1936-37 published a series of articles on the subject [see this Bulletin 1937 v 34 858]. There seems to have been no important difference between the clinical features of the disease and those of sandfly fever in other countries.

In the summary of the experimental work by Russian observers, reference is made to successful immunization of human beings by injecting the virus after previous injections of convalescent serum and to the passage of the virus through the eggs of experimentally infected sandflies to their offspring and through the yolks of hens' eggs up to 48 passages.

References are given to 20 articles on the subject by Russian workers during the years 1936-1940

PLAGUE.

DEVIGNAT R. Aspects de l'épidémiologie de la peste [Standardization of Epidemiological Surveys in Plague.] *Bol Oficina Sanitaria Panamericana* 1945 Oct v. 24 No 10 895-906 1 chart & 1 fig English summary

In an introduction Dr Devignat refers to the classical opinion originated by the Indian Plague Commission that the rôle of vector in plague epidemic and epizootic attaches to the flea *Xenopsylla cheopis* and that subsidence of an epidemic is correlated with variation in the flea index. He cites exceptions and objections to this view and brings forward a scheme of standardization for the epidemiological study of plague which would apply to local conditions and yet be comparable with conditions prevailing elsewhere. He has applied his scheme to the study of plague 1941-1943 in the region of Lake Albert in Belgian Congo. The scheme now proposed permits the inclusion of the *Rattus coucha ugandae* of Blukwa with its infestation by *Xenopsylla* fleas among the domestic rodents.

There are according to Devignat three fundamental plans of plague activity, the sylvatic and domestic murine plans and the human plan with six methods of possible contagion. These are intersylvatic, interdomestic, interhuman, sylvo-domestic, sylvo-human and domestico-human. He has devised a linear equation to determine Q the common index of epidemiogenic or epizootic transmissibility based on modes of transmission. Various constants enter into the equation such as K the constant of receptivity k, k, k'' constants of vection and variables in the shape of indices i, i, i'' rat flea indices and t, t, t flea burrow indices. The technique for development of this standard scheme is given in detail. A chart is figured to show the application of the plan to Lake Albert. It may be noted that pulmonary plague is excluded from this suggestion of a standard plan to summarize all the epidemiological aspects of plague in various countries. *W. F. Harvey*

MACCHIAVELLO A. Instrucciones para el diagnóstico tratamiento y aislamiento de enfermos de peste bubónica, y para la recolección de muestras destinadas a exámenes de laboratorio [Instructions for Diagnosis, Treatment and Isolation of Plague Cases and for Laboratory Specimens.] *Bol Oficina Sanitaria Panamericana* 1945 Aug v. 24 No 8 704-12.

These instructions are set out in a series of 23 detailed and clear paragraphs. They should leave no practitioner who is confronted with the possibility of plague in any doubt what he should do. The first paragraph reads—The present ordinance establishes the rules for diagnosis isolation and laboratory examination including human autopsy of bubonic plague as well as the simple examination required in every notification of certain or suspected human or rodent plague. The several instructions follow and the article ends with the printed form for cases of plague.

W. F. Harvey

WARSON N E. & McILHARON Margaret C. Plague Treatment of Experimental Animals with Streptomycin, Sulfadiazine, and Sulfapyrazine. J. Lab. & Clin. Med. 1946 Mar., v 31 No 3 323-32, 1 fig.

Sulphonamide therapy has been extensively tested in plague, and the value of sulphadiazine has been established. The authors have now tested streptomycin a product of *Actinomycetes griseus* and appropriately controlled and compared with sulphadiazine. Mice and guinea pigs were the animals used and infection was induced by inoculation and, also in guinea pigs more naturally through fleas. Streptomycin was given subcutaneously dissolved in normal salt solution. Sulphonamides were suspended orally by syringe or in capsules. This therapy was given after infection, and indicated that streptomycin had definite value. Summarizing the authors say — (1) Three hundred and thirty four white mice were inoculated with plague and one-half were treated in groups with different amounts and varying dosage of either streptomycin, sulfadiazine or sulfapyrazine. The other one-half were used as controls. Under the treatment schedules finally adopted, while all the corresponding controls among each lot of from eighteen to twenty, from sixteen to eighteen survived died of plague. (2) Forty-eight guinea pigs were likewise inoculated and one-half were treated with streptomycin in two groups after clinical evidence of infection had developed. All survived but eight had residual buboes at necropsy. Twenty-three controls died with plague. (3) One hundred and six guinea pigs were infected through flea transmission. After the disease was evident clinically fifteen were treated with streptomycin and fourteen survived. Fifteen received sulfadiazine and fourteen survived. Three survived among all the survivors had residual buboes at necropsy. (4) Clinical recurrences appeared frequently under the treatment schedules used with streptomycin and sulfapyrazine but not with sulfadiazine.

KLINGENSMITH, C. W. A Note on the Natural Occurrence of Fluoroacetic Acid, the Acid of the New Rodenticide "1080". Science 1945 Dec. 14 622-3.

The sodium salt of monofluoroacetic acid has recently been advocated as a rat poison [this Bulletin 1946 v 43 331]. The acid itself has been shown by MARAIS (Onderstepoort J. Vet. Sci. 1943 v 18, 203-6 1944 v 20 67-73) to be the toxic principle of *Dichapetalum* (= *Chorizandra*) cynosuroides called Gifblaar a well known stock poison in South Africa. Another species in the genus *D. torrensii* is a notorious poison in Sierra Leone where it has been used by colonists for destroying rats.

[MONSANTO CHEMICAL COMPANY "1080" Rodenticide to be sold only to Pest Control Operators. Pests. 1946 Jan. v 14 No. 1 28.

Owing to its very high toxicity "1080" will not be on sale at any time to the general public. The lethal dose for man is believed to be one-fiftieth of an ounce — about 8 mgm. per kgm. for a man of 60 kgm. (10 stone). No antidote is known. It is recommended for use at 0.04 per cent. on oats, one-fiftieth of an ounce to three poisoned rats. Cases of deaths of dogs and pigs, presumed to be caused by eating poisoned rats, are recorded. Though not stated here, "1080" is sodium fluoroacetate. [A verbally identical note except for statement about danger to domestic animals, occurs in *Chemurgic Digest* 1946 Jan. v 5 22. There was an even briefer summary of the same press release in *Chem. Engng News* 1945 v 23 2367.]

CHOLERA.

YACOB M. & CHAUDHRI J. R. A Note on the Spread of Cholera Infection through Aerated Drinks. *Indian Med Gaz* 1945 Dec. v 80 No 12 634-6

With the outbreak of epidemic cholera public health authorities tend to recommend or impose standard regulations as to food and drink upon the populace. Many of these regulations have been handed down for generations and have not been subjected to actual test. This certainly applies to aerated drinks and perhaps to ice. The authors have tested soda water and lemonade for their capacity to promote the growth of cultures of *V. cholerae* or as the case may be their vibriocidal action. These waters have a pH of 6.8 as compared with control water of 7.8 and the gas which was not allowed to escape had a pressure varying from 125 to 150 lb. For the ice experiments water infected with cholera culture was converted to ice and was used after 24 hours to cool the aerated drinks. The conclusions are very interesting — The experiments described show conclusively that given sufficient time an aerated drink even if infected with cholera is rendered harmless by its own action. It is not certain whether the vibriocidal action is due to lowered pH or to pressure of the gas although under the same experimental conditions only one bottle out of five containing non-aerated lemonade gave a growth of cholera vibrios. It also seems likely that cholera infected water when converted into ice and served in drinks may also not prove harmful. W. F. Harvey

BACILLARY DYSENTERY

CHEEVER F. S. Dysentery Outbreak aboard Naval Vessels in San Pedro Bay, Philippine Islands. *U.S. Nav Med Bull* 1946 Apr., v 46 No 4 479-84

During the months of July and August 1945 an outbreak of bacillary dysentery occurred on ships of the Third Fleet and Service Squadron 10 anchored in San Pedro Bay Philippine Islands. More than 6,000 cases were reported during this period. The etiologic agent was *Shigella flexneri* III (VIII). The disease was clinically mild and only 3 deaths were recorded.

The original focus of infection was apparently the native population. Naval personnel appeared to have become infected through contact with native food and drink either ashore on the recreation beaches or afloat by patronizing bumboats. The subsequent inter ship spread was probably caused by polluted

harbor water (small-boat personnel being particularly hard hit) and by personal contact between the crews of two or more ships that were tied up together. Once the disease became established aboard a crowded ship, it proved extremely infectious and hard to control in spite of the usual sanitary measures. Infected food handlers, convalescent carriers and subclinical cases probably contributed to the spread of the disease. Flies may have been involved in the genesis of the epidemic on the beach, but they played no role in the subsequent spread of the disease in the anchorage. No evidence was disclosed that fresh water obtained by distillation of harbor water was contaminated, and the epidemiologic picture was not one of massive water-borne infection.

Experimentally it was proved that strains of the specific organism recovered comparatively late in the epidemic could survive at least 2 days in sea water and that they were relatively resistant to the bacteriostatic action of sulfa diamine and sulfathiazole. This property of drug fastness is one explanation for the noteworthy failure of chemoprophylaxis to check the epidemic."

AMOEBIASIS AND INTESTINAL PROTOZOAL INFECTIONS

BROWN, A. G. Experiences with Amoebiasis in an Evacuation Hospital. *War Medicine* Chicago 1945 Nov.-Dec., v 8 No. 5 319-24

In a 400-bed American Evacuation Hospital, during two years' service in North Africa and in Europe, intestinal amoebiasis was diagnosed in 243 patients and hospital personnel. The majority of these had been hospitalized for gastrointestinal symptoms. A survey of the hospital personnel, after 18 members had been treated for acute amoebic dysentery, showed that 65 of 298 (21.8 per cent.) were infected with *Endamoeba histolytica*. Diagnosis was at first made in the usual manner by the examination of fresh specimens of stool. Subsequently Schaudinn-fixed smears were stained with iron-alum-haematoxylin, as difficulty was experienced in identifying cysts and "precysts" in fresh preparations. A rapid method of fixation and staining, taking little more than one hour is described.

Treatment, where undertaken, was daily for 10 days with emetine injections, accompanied, and followed after a week's interval, by courses of carbarsone or chinolone, as recommended by U. S. Army Headquarters, North Africa. One week after completion of the second course, three stools were checked. In only 1 case were *Endamoeba histolytica* cysts still present after the two courses, and this patient was evacuated for further therapy. In a few cases amebae other than *Endamoeba histolytica* were not all destroyed by the course of therapy."

[The difficulty experienced generally by service pathologists in differentiating the morphologically characteristic cysts of the intestinal protozoa in fresh unstained preparations of faeces is perhaps not unduly hard to understand. But the ease with which these pathologists can specifically identify, in fresh preparations and after a saline purge, the much less obviously characteristic vegetative stages of these same parasites is more difficult to grasp. The apt "it moves—it's an amoeba. It has engorged red cells—it's *histolytica*" reasonably accurate for the detection of the acute amoebic dysentery, not be regarded as adequate for the purpose of a survey of

infection rates. This does appear to have been recognized to some extent in the study recorded in the present paper as staining methods after fixation were adopted.]

A R D Adams

LUCAS R. B. Culture Methods in the Diagnosis of Amoebiasis. *J Roy Army Med Corps* 1945 Nov v 85 No 5 249-51

Using Loeffler's serum slopes covered with Ringer's solution to which egg albumin and rice starch were added the author attempted to cultivate *E histolytica* from the faeces of 405 patients sent to the laboratory of a military hospital in an area in which amoebiasis was endemic. *E histolytica* was discovered in 18 by direct microscopical examination and all these gave a positive culture. In addition positive cultures were obtained in 24 cases in which amoebae were not discovered by the microscope. It is concluded that culture of faeces for *E histolytica* as a routine measure can be of considerable value in the diagnosis of amoebiasis.

LAWLESS D K. Detecting Intestinal Protozoa. Saline-Iron-Hematoxylin Solution for Wet Smears. *Amer J Trop Med* 1946 Jan v 26 No 1 133-4

Cysts and trophozoites of intestinal protozoa in faeces are easily distinguished from similar objects and from the background if fresh slide preparations are made with the following mixture: normal salt solution 75 cc., 0.5 per cent. haematoxylin solution 10-15 cc., 4 per cent. ferric ammonium sulphate 0.25 cc. A small particle of faeces is emulsified in a drop of the solution to make a thin film under a coverslip: the protozoa are seen against a black-stained background.

J F Corson

HAMZAH N A. Amoebic Appendicitis. *J Palestine Arab Med Ass* 1946 Mar v 1 No 3 72-4

Of 50 appendices removed consecutively at the Government Hospital Haifa Palestine 13 had amoebic ulcers (amoebae present) 9 had other ulcers 21 had diffuse infiltration and 7 had worms 4 were gangrenous but none of these was amoebic.

In 12 of the 13 cases with amoebic ulcers the appendix appeared normal or slightly thickened externally and the mucosa looked normal except for two or three greyish sanguineous sloughs covering ulcers with undermined edges: the ulcers were mostly limited to the mucosa but in a few cases they extended to the serous coat.

These 13 cases were diagnosed before operation as subacute appendicitis: they had a history of slight pain in the right lower abdominal quadrant for months or even years and tenderness over McBurney's point was present in all.

The author concludes that from 20 to 30 per cent. of cases of subacute or chronic appendicitis in Palestine are of amoebic origin. If amoebae are found in the stools before operation medical treatment should first be given and operation should be done later to prevent relapse.

J F Corson

GOLDEN R. & DUCHARME P. The Clinical Significance of Deformity of the Cecum in Amoebiasis. *Radiology* 1945 Dec. v 45 No 6 565-80 6 figs [14 refs]

Amoebiasis is common in the United States and its diagnosis may be difficult. Sixty-seven patients (in 58 of whom *E histolytica* was recognized in the stools and in 9 of whom this organism was assumed to be present though not actually found) were radiographed after a barium meal (27) or after a barium enema (18)

or after both (22). Thirty three of the 67 patients suffered from diarrhoea, 9 complained of various abdominal symptoms but not of diarrhoea and the remaining 25 were either free from abdominal symptoms (18) or there was inadequate information in respect of these (7). In 30 of the 67 including 18 of those complaining of diarrhoea, and 21 of the microscopically proven cases of amoebiasis deformity of the caecum was observed radiographically. This deformity varied considerably in some cases it was slight and consisted of narrowing of the tip in others the caecum was markedly shrunken, but its outline was generally smooth and only rarely irregular. Where deformity occurred there was usually localized tenderness over the caecal area and in some cases pressure apparently accentuated the deformity. In no case was narrowing or intrinsic deformity of the terminal ileum seen, although in one instance obliteration of the folds and the smoothness of the shadow suggested oedema of the ileal mucosa. This cleared after specific anti-amoebic treatment.

Five patients with caecal deformity were re-examined after treatment. In four there was "relaxation of the caecum" suggesting improvement. In the fifth case with a markedly shrunken caecum there was no change. From this the authors deduce that the caecal changes produced by amoebiasis in its later stages are irreversible. They conclude that caecal deformity demonstrable on radiography is likely to be seen in over one-third of cases of amoebiasis more particularly in those with intestinal symptoms it may give a valuable pointer to the diagnosis but its absence does not exclude a diagnosis of amoebiasis.

ISAAC F Roentgen Findings in Amebic Disease of the Liver *Radiology* 1945 Dec., v 45 No. 6, 581-7 5 figs.

Amoebic involvement of the liver is the most common complication of amoebic dysentery. It is more common in visitors to the tropics than in the Natives. Of 222 cases of amoebic dysentery in an Army Hospital overseas 32 (14 per cent.) suffered embolic liver infection. Two stages of liver trouble were seen a diffuse hepatitis (without jaundice) and, later amoebic abscess or multiple abscesses. Clinical differentiation of the stages is difficult unless aspiration or drainage is done. These are rarely necessary if early specific treatment is instituted, and so most of the author's cases were designated amoebic hepatitis. On X-ray examination about half his patients showed no signs or at most downward enlargement of the liver. These were probably cases of diffuse amoebic hepatitis. The other half showed doming of the right diaphragm with flattening of the costophrenic sinus. The doming may be restricted to the outer portion of the diaphragm or it may be in the mesial portion and the cardiophrenic angle is then obliterated. Sometimes the elevation is limited to the middle portion of the right diaphragm and the costophrenic and cardiophrenic angles are sharpened. Elevation of the right diaphragm is the most unequivocal sign of amoebic liver abscess. On screening limitation of movement with sluggishness or fixation of the right diaphragm may be seen. The right lower lung field may show changes resembling an atypical primary pneumonia owing to compression of the base by the raised diaphragm or to an interstitial pneumonitis or to partial atelectasis. There may be a pleural reaction with thickening of the pleura and effusion into the costophrenic sulcus. This probably arises from rupture of the liver abscess into the right pleura and the chest signs may then mask the causative liver lesion.

Most cases of amoebic liver disease respond to medication without operative interference or aspiration. Illustrative cases are cited, with reproductions of radiographs.

[No mention is made of the possibility of variation in the site of amoebic abscesses in the liver. It is apparently assumed that these *always* occur in the upper portion of the right lobe.] *A R D Adams*

COTTRELL J D & HAYWARD G W. The Effects of Emetine on the Heart. *Brit Heart J* 1945 Oct. v 7 No. 4 168-70 2 figs

Changes in the electrocardiogram blood pressure and pulse rate produced by emetine and emetine bismuth iodide have been studied in soldiers under treatment for amoebiasis. All were otherwise healthy and the initial cardiograms were normal. Diminution or inversion of the T waves occurred in one or more leads in 25 out of 32 cases receiving emetine and in 12 cases there was an increase in the P R interval of from 0.02 to 0.04 sec. Similar changes occurred during treatment with emetine bismuth iodide 7 out of 8 cases showing diminution in T waves and prolongation of the P R interval. The cardiogram returned to normal 8-12 days after the completion of treatment. The effect on the blood pressure and pulse rate of both drugs was insignificant and in no case was there any clinical evidence of myocardial insufficiency.

BERBERIAN D A. Treatment of Lambliasis with Acranil. *Amer J Trop Med* 1945 Sept. v 25 No 5 441-4 [27 refs.]

The author has treated 50 cases of giardia infection in children with Acranil [see this *Bulletin* 1945 v 42 909]. The dose of the drug varied around 0.1 gm. twice or thrice daily for five days. In some cases an initial dose of 0.2 gm. to 0.5 gm. commenced the course. Following the treatment five weekly examinations for giardia infection were carried out. It appeared that in all the 50 children as well as in three adults Acranil had eradicated the infection. It is noteworthy that other protozoal and helminthic infections were unaffected by the drug which was well tolerated by all the children though a slight coloration of the skin occurred. *C M Wenyon.*

RELAPSING FEVER AND OTHER SPIROCHAETOSSES.

ADVIER. La fièvre récurrente et ses accidents nerveux. [Relapsing Fever and its Nervous Manifestations.] *Les Grandes Endémies Tropicales* (Onzième Année) 1939 Paris pp 33-48.

A useful summary of the history of relapsing fever with special reference to the occurrence of the disease in the French Colonies. The title of the article however is somewhat misleading since little more than two pages are concerned with relapsing fever as it affects the nervous system. *E Hundle*

LEPROSY

NEWMAN P P. A Visit to an Indian Lepar Colony. *Brit Med J* 1946 Apr 20 616.

PRABHU M N. Leprosy of the Upper Respiratory Passages. *Leprosy in India* 1946 Jan. v 18 No 1 10-12.

The author who was resident medical officer in charge of ear nose and throat hospital cases at a Madras hospital reports the results of examinations

carried out at the Silver Jubilee Leprosy Clinic including bacteriological examinations during a period of six months. The evidence indicates that nasal infections are the result of general rather than of local infections. In simple macular neural leprosy the nose is seldom if ever infected but in major tuberculous leprosy nasal lesions are not uncommon. The nasal mucous membrane first becomes congested and oedematous with greenish, whitish or yellow inflammatory spots, and it bleeds easily. *Lepra* bacilli can be found in small number only and blocking of the nose results with the formation of crusts. Later ulceration occurs, the septum may be perforated and destruction of cartilages with deformities may result. The mouth tongue and pharynx may become involved in advanced lepromatous disease and perforations of the hard or soft palate may resemble those due to syphilis. Nodules occur and also leprosy glossitis which may be extremely painful. In such cases the larynx may become similarly affected, first with thickening of the epiglottis with spread to the vocal cords either as an ulcerative or a fibrotic condition. Much swelling and oedema may necessitate tracheotomy.

L. Rogers

Mix E. Elephantiasis and Septic Infection. *J Trop Med & Hyg* 1945
Dec-1946 Jan v 48 No 6 145-8, 3 figs.

In this paper a comparison is made between lepromatous leprosy and filarial elephantiasis as regards secondary septic infection and the development of pachydermatous conditions in both cases associated with lymphatic obstruction and with periodic inflammatory changes. In the filarial disease the febrile attacks are associated with monthly parturition of the adult female worms, with the production of very large numbers of embryos as shown by ROGERS, and are accompanied by lymphangitis which may be of septic origin. Allergy is also thought to play a part in this process. In lepromatous leprosy the frequent febrile reactions may similarly be caused by secondary septic organisms by blocking of small lymphatic vessels and by allergic reactions like those produced by the injections of protein matter derived from *lepra* bacilli, such as followed by the use of Dharmendra's lepromin, or by the administration of iodides, as shown by Vinn himself. An illustration is given which shows great swelling of the face during an acute *lepra* reaction and another shows a pachydermatous condition of the face. Attempts to control *lepra* reactions by sulphonamide drugs failed, but more recently promin and diasone, which inhibit the growth of the tubercle bacillus have proved more effective, especially in inflamed eyes and ulcerated noses. Sulfaseptazine given intramuscularly cleanses septic leprotic ulcers rapidly. The action of penicillin resembles that of diasone and promin in advanced lepromatous cases and as penicillin is inert against tubercle bacilli and probably against *Mycobacterium leprae* the action of all three is probably on the septic infection. All this points to septic infections playing an important part in the causation of *lepra* reactions.

D & SERRA D T. Lepromin Skin Tests in Boeck's Sarcoid. *Amer J Med* 1946, Nov., v 23 No. 6 519-21 1 fig

tests in ten cases of Boeck's sarcoid, including
11. The clinical symptoms were typical examinations. In seven the lepromin also negative to tuberculin. In the reactions and in two of them tuberculin of active tuberculosis gave positive that Boeck's sarcoid is an attenuated

L. Rogers.

HARRELL, G T & HORNE S F The Reaction to Lepromin of Patients with Sarcoid or Tuberculosis compared with that of Patients in General Hospitals with a Discussion of the Mechanism of the Reaction *Amer J Trop Med* 1945 Nov. v 25 No 6 523-35 7 figs. [17 refs]

This paper also deals with lepromin tests to determine if Boeck's sarcoid may be caused by the *Mycobacterium leprae* as suggested by the clinical and pathological resemblances between certain cases of sarcoid and tuberculoid leprosy. It deals with 70 patients tested with lepromin: they included 5 with sarcoid, 5 with active tuberculosis, 41 with healed or inactive tuberculosis who were suffering from a variety of chronic diseases, and 18 with a variety of acute and chronic diseases. The authors regard early erythematous reaction with lepromin as less specific than the later infiltration and ulceration which occurs at the site of the lepromin injection in positive cases. Full details of the tests are given and the results tabulated. From a study of these the authors come to the following conclusions. In patients with sarcoid the reactions are slight and infrequent; they give no indication that sarcoid is atypical tuberculoid leprosy. In a control group in the U.S.A. the incidence of intense or moderately intense lepromin reactions is less than in endemic areas of leprosy in the tropics. The high incidence of strong late lepromin reactions in active tuberculosis suggests the presence of common sensitizing antigens, possibly soluble protein or polysaccharide. It is also suggested that a lipid may be the active chemical fraction. If tuberculosis can be ruled out, lepromin may prove useful in the diagnosis as well as the prognosis of leprosy. The authors suggest that leprosy like tuberculosis may be a disease of high contagion, slow progression and high curability, requiring repeated regular exposures to the infecting organism. Attempts should therefore be made by frequent inoculations of living organisms into animals over a long period, with a view to their infection. As the living monocyte appears to furnish a substance essential for the growth of the *Mycobacterium leprae*, attempts should be made to cultivate it by the inoculation of tissue cultures of monocytes or of chick egg chorio-allantoic membrane with infected material.

L. Rogers

CORRECTION

Professor DE SOUZA ARAUJO has called attention to the fact that for the experiments referred to in the abstract in this *Bulletin* 1945 v 42 1010 he used his original cultures of acid fast bacilli isolated from leprosy material and not emulsions of material rich in Hansen's bacilli as stated in the abstract — Ed

SLOAN T B M The Role of Propaganda in the Control of Leprosy *Leprosy in India* 1946 Jan. v 18 No 1 15-22.

The subject is dealt with on very general lines with special emphasis on education of the public. The author thinks that too much attention is being paid in India to treatment rather than to isolation of infective cases. Legislation is not needed for the control of patients with neural leprosy, but more persuasion is required for the isolation of lepromatous cases. Propaganda should be prepared by a professional publicist and radio talks and discussions should be arranged. Posters and slogans should be displayed in schools and public buildings so as to combat common prejudices among the illiterate. The author supports the view that the word 'leper' should not be used. School teachers should be instructed on the subject as well as employers of labour who should know that 75 per cent of all cases are uninfected. L. Rogers

BLOSS J F E. The Control of Leprosy among the Azande, Anglo-Egyptian Sudan. *Trans. Roy Soc. Trop Med & Hyg* 1946 Apr v 39 No 5 423-36 1 map.

This valuable report brings up-to-date information on work for the control of leprosy in the heavily infected humid southern Sudan where much leprosy was discovered during operations against an outbreak of sleeping sickness. Dr ATKEY the P.M.O. originally ordered a leprosy survey which was carried out by Dr CRICKSHANK in 1929 with the discovery of 8 400 cases within two years, representing 3.3 per cent. of the population whose diet was deficient in animal proteins. In 1929-30 a total of 5,500 lepers—some 80 per cent. of the known cases in the district—were transferred with their families to two large settlements, at Soutras Yuba and Li Rangu, and treated mainly by Alepol intravenously which was found to be the most effective preparation. By the end of 1931 30 per cent. of the patients had improved, and 40 per cent. more were discharged as quiescent and uninfected. Advanced lepromatous cases were now segregated in special camps to diminish the chances of infection. In 1935 WOODMAN (*Sudan Med. Serv Ann Rep* 1935) estimated the disease incidence at 7 per cent. of the population and reported that the records of 3,500 cases [see this *Bulletin* 1938 v 35 295] showed good results from treatment with chaulmoogra derivatives for periods not exceeding 3 or 4 years after which no further benefit accrued. He considered that the Li Rangu settlement, with 25 sq. miles of land then the largest in Africa, was of value in isolating the most infective cases and in facilitating treatment. In 1935 the Li Rangu settlement figures were —

Advanced cases segregated	204
Under observation or treatment in settlement	1 021
Discharged cases, cures and quiescent, living in settlement	951
Discharged cases living outside settlement	513
Total	2 689
[Total cured or quiescent (951+513) 1 464 (54.4%)]	
Outside cases which had never been in the Settlement	809
Total	3 498

This settlement however was overcrowded.

In 1939-40 a new survey and census was made and yearly inspection of the whole population was being carried out in 1941 a card index overcame difficulties in registration of patients. The total known cases had fallen to 1,855 and the new cases had declined from 283 in 1939 to 186 in 1941 and 86 in 1942.

Conditions in the settlement have now been improved, and agricultural work is paid for this furnished almost all the food crops for much increased rations. During the war Alepol supplies ran out and treatment has been disappointing. The age incidence now shows that less than 12 per cent. of the known cases are in persons under 20 years of age, against 21 per cent. in 1930. "This points to (a) the disease being under control, and (b) that a decrease rather than an increase in the number of cases is to be expected in the future." A gradual decentralization is now being aimed at by organizing a number of local, small, chief's colonies in place of one very large settlement, coupled with an increase in public health activities and improvement in the standards of living.

L. Rogers.

CHANDY P J. The Problem of the Discharged Patient. *Leprosy in India* 1946 Jan., v 18 No. 1 13-14.

This is a short note by the medical officer of the Fyzabad Leper Home and Hospital, which deals with 40 cases discharged during the previous six years.

Patients with arrested disease are often unwilling to leave the institution to make room for more suitable patients on account of social prejudices and difficulty in obtaining employment under favourable living conditions. Eight of the 40 discharged cases had relapsed not a very high rate but enough to make an employer loath to run any risk. Discharged patients may meet with difficulties in returning to live in their own villages patients who show any deformity are especially viewed with suspicion. Two developed tuberculosis which is common among leprosy patients. A few can be employed after recovery in leprosy institutions. The author suggests that industrial and agricultural settlements should be started near each leprosy institution which will ultimately become self-supporting and provide the best solution of the problem.

PRUDHOMME R. O. Conservation de la vitalité du bacille de Stéfansky dans des lépromes desséchés [Conservation of the Vitality of Stéfansky's Bacilli.] *Bull Soc Path Exot* 1944 v 37 Nos 11/12 338-44

MARCHOUX and SOREL (*Ann Inst Pasteur* 1912 p 1) have shown that when Stéfansky's bacilli of rat leprosy are dried for two days over sulphuric acid in a vacuum they are no longer infective to rats and that they also die when preserved for 15 days at 37°C in physiological saline. The vitality of the organisms can be tested without animal inoculation if to 1 cc. of a pure emulsion of the bacillus is added 1/20 cc. of a solution of orthocresol-endo-2-6 dichlorophenol N/10 000 in boiled distilled water and the blue mixture is placed in an ampoule which is sealed after removal of the contained air. If the bacilli are living at the end of 24 hours the contents of the ampoule will have become decolourized but not if they are dead. By the use of this test and by the inoculation of rats the authors have found that bacilli contained in a leproma frozen and crushed at -28°C. and then dried and kept in a vacuum at from 0° to 4°C. retained their virulence for rats for over one year but if kept in the presence of air they died. Lepromata dried over sulphuric acid also kept their virulence for over a year in a vacuum, but not in air.

HELMINTHIASIS

TARR L. Effect of the Antimony Compounds, Fuadin and Tartar Emetic, on the Electrocardiogram. A Preliminary Report. *Bull U.S. Army Med Dept.* 1946 Mar v 5 No. 3 336-9 1 fig

Electrocardiograms were taken in 150 patients who had returned from abroad where they had suffered from schistosomiasis and had been treated with Fuadin or tartar emetic or both at times varying from 22 to 112 days previously. They showed no clinical symptoms or signs of organic heart disease and all except four of the electrocardiographic tracings were normal. In 66 patients ova of *Schistosoma japonicum* were present in the faeces and the patients were given further treatment with antimony. Electrocardiograms were taken under standard conditions before during and after this treatment.

Fuadin—Intramuscular injections every other day of a 6 per cent solution to a total of 65 cc. (0.566 gm. of antimony) in 14 injections—was given to 28 patients, while tartar emetic—intravenous injections every other day of 0.5 per cent. solution to a total of 320 cc. (0.576 gm. of antimony) in 15 injections—was given to the other 38 patients.

The only change in the electrocardiogram was a decrease in the voltage of the T wave of different degrees which the author classifies as one plus two plus,

three plus and four plus, respectively only the last two being significantly different from normal tracings these however might easily have been interpreted as indicating myocardial damage or even coronary occlusion. The three plus or four plus changes occurred in 12 (31 per cent.) of the 38 patients treated with tartar emetic and in only two of the 28 who were treated with Fuadin. There was no apparent relationship between the maximum changes in the electrocardiogram and toxic effects of the drugs and in no case was the course of treatment altered because of such changes. The return to a normal cardiogram began some days after the end of treatment and was usually complete within a month.

The author regards the electrocardiographic change as a transient reversible effect of trivalent antimony on the heart and its only importance is the possibility of mistaking it for serious myocardial damage. [The author somewhat misrepresents the findings of MAITZER and KRAUSE (this Bulletin 1940 v 37 487) in 7 of their 12 cases the electrocardiogram showed either a definitely pathological tracing during the antimony treatment (3 cases) or a curve which "suggests the suspicion of an altered function of the cardiac muscle" (4 cases)]

TORRES C. M. & PINTO C. Mecanismo de eliminaçào dos ovos de *Schistosoma mansoni* estudado no tatu (*Euphractus sexcinctus*) [Mechanism of Elimination of the Eggs of *S. mansoni* in the Armadillo.] 4w Acad Brasileira de Ciencias 1945 Dec. 31 v 17 No 4 271-2 2 figs. on pls.

The armadillo to which the authors refer died 94 days after infection, and at autopsy 86 female and 23 male *S. mansoni* were found in the liver and two of each sex in the pancreas. In the walls of both small and large intestine there were numerous granulomata and eggs, but there were interesting differences in the distribution of the lesions between the small and the large intestine. In the small intestine, granulomata and eggs were always localized in the submucosa, never above the muscularis mucosae the small intestine is evidently not the route by which eggs are passed to the exterior. In the large intestine on the other hand, the granulomata and eggs are most numerous in the mucosa itself, and are rarely seen in the submucosa. Elimination of eggs into the faeces is therefore exclusively performed in the large intestine.

The mechanism of elimination is complex. It depends on various factors — (1) the structure of the intestinal wall and its vessels (2) the extrusion of the eggs from the capillaries and their fixation in the mucous coat at the level of the fundi of the crypts of Laeberkuhn (3) the formation of cellular infiltration round the eggs (4) histolysis of the walls of the crypts by products elaborated by the eggs (5) elimination to the exterior along with the intestinal secretions. The important part of this process is the elaboration of histolytic substances by the embryo. In the large intestine the authors found cystic dilatation and hypertrophy of the glands which may have been the precursors of adenomatous polyp.

HILLEMENT P., VARAY A., DERRAY J. R. & DUGUET Mme A propos d'un cas de distomatose hépatique. [A Case of *Fasciola hepatica* Infection.] Bull. et Mém. Soc. Méd. Hôp. de Paris 1946 Nos. 1/2, 50-52.

The patient a man aged 30 was first treated in August 1942 for irregular vomiting and diarrhoea, without benefit. In January 1943 he was again examined and the diagnosis of infestation with *Fasciola hepatica* was suggested by blood examination which showed 67 per cent of eosinophiles, and was confirmed by finding the ova in the faeces.

He developed pleural effusion at this time associated with fever (40 C) on the first day but the temperature fell to 38 C next day before treatment with sulphonamides was begun and became normal a few days later. Lymphocytes formed 70 per cent of the cells of the pleural fluid and culture of the fluid remained sterile. The effusion meanwhile disappeared without any apparent involvement of the lung.

A week later (7th February) treatment with emetine was begun seven injections of 8 cgm. [$1\frac{1}{2}$ grain] were ordered but by a mistake a single dose of 40 cgm. [6 grains] was injected and caused no untoward symptoms. Altogether he got 80 cgm. of emetine. Improvement was rapid the eosinophilia decreased to 31 per cent. in a few days and his weight increased by 2 kgm.

Six months later (August) treatment with stovarsol was begun [no mention is made of faecal examination] and the eosinophilia decreased to 8 per cent and in January 1944 it was 5 per cent. He was then given another course of emetine injections and recovered completely.

The author suggests that the pleural effusion was a pleural form of Loeffler's syndrome. The rapid improvement after the first course of emetine leads him to think that it might have been due to the large dose of emetine given by mistake. [For other references to infestation of man with *Fasciola hepatica* see this *Bulletin* 1942 v 39 14 703 1943 v 40 253 472 1944 v 41 677 1052]

EDWARDS C Cerebral Cysticercosis without Epilepsy *Lancet* 1946 Apr 6 500-501 1 fig on pl.

An airman aged 42 was invalided to England from the Azores after 5 months service in July 1944 because of two attacks of aphasia one in May and the other in June of that year. He had lived in the Middle and Far East from 1919 to 1925 and had since lived in England. In 1937 he developed a vague frontal headache which had been almost constantly present ever since. In 1942 he awoke one morning to find that the left half of his field of vision was impaired and this has since remained unchanged.

Medical examination in July 1944 showed incongruous homonymous hemianopic defects involving chiefly the lower left quadrant. No abnormality was seen by radiography of the skull. Lumbar puncture was done and the cerebrospinal fluid showed a pressure of 90-100 mm. of water and normal Queckenstedt test there were no cells protein 0.07 per cent a very slight increase in globulin, negative Wassermann reaction and the Lange gold curve was +43321000. The blood also gave a negative W.R. there were 8,300 white blood corpuscles and a differential count showed polymorphonuclears 60 per cent lymphocytes 35 per cent. eosinophils 3 per cent., and monocytes 2 per cent.

On the 4th day after the lumbar puncture an irritable rash appeared on the thighs legs elbows and forearms and lasted for about 4 days.

On suspicion of a neoplasm being present the chest was radiographed and this disclosed the presence of numerous small calcified bodies in the muscles and subcutaneous tissues which were seen also all over the body. They were obviously cysticerci and careful search showed two subcutaneous nodules in the epigastric region and one in the left upper arm. An encephalogram was taken and showed short runs of waves with a frequency of 22 per sec. in both parietal regions. These interrupted a stable dominant frequency of 10 per sec. The disturbances which were numerous were considered to be epileptic in type. The patient was invalided from the Service his only symptom then being a slight headache.

The author notes that the incubation period (at least 12 years) is one of the longest recorded. DIXON and HARGREAVES [this Bulletin 1945 v 42 907] reported one of 20 years. Reference is also made to papers by MAC ARTHUR [this Bulletin 1934 v 31 334] and MARSH [*ibid* 788 see also ELSAESSER, *ibid.*, 1946 v 43 228] J F Corson

DICK, G W A. & MCCARTHY D D The Absence of Anaemia in Hookworm Infestation in East African Personnel. *East African Med J* 1946 Jan v 23 No. 1 19-22. [13 refs.]

McCarthy [this Bulletin 1931 v 28, 21] made observations on natives in Pemba Island who had severe anaemia associated with hookworm infestation. The more heavily infested patients were treated with oil of chenopodium, iron and arsenic, as well as being given a full diet, while the less heavily infested patients were given a full diet extra eggs and fruit and 15 gm. of marmite daily but received no drugs. He concluded that the cause of anaemia associated with hookworm infestation was an inadequate and probably deficient diet.

Dick made observations, recorded in the present paper, on 67 East African native soldiers in whose faeces hookworm ova were the only indication of the presence of pathogenic parasites (*Strongyloides stercoralis* and *Trichuris trichiura* were regarded as non-pathogenic). The controls were native soldiers with no evidence of any intestinal infestation. The observations consisted of erythrocyte counts and estimations of haemoglobin in the blood. The average number of erythrocytes (4.9 millions per cmm) was the same for the patients and the controls and the average haemoglobin content was slightly higher in the patients (101 per cent. or about 17 gm. per 100 cc.) than in the controls (99 per cent.).

The authors discuss the significance of their observations and conclude that hookworm infestation, unless it is very heavy, does not cause anaemia in East African natives who are well fed and are living under good conditions. When anaemia occurs it is due partly to deficiency of blood-building material (protein and iron) in the diet and partly to removal of blood by the hookworms. In such cases a good diet is more important than anthelmintics. J F Corson.

CRUZ, W O & DE MELLO R P Profilaxia da anemia ancilostomótica. Síndrome da carencia. [Hookworm-Anaemia a Food Deficiency Syndrome. Its Prophylaxis.] *Mém. Inst. Oswaldo Cruz* 1945 Apr., v 42 No. 2 401-48, 11 graphs. [19 refs.] English summary

[An account of an interesting series of experiments.] The fact has been observed that severe anaemia associated with ankylostomiasis occurs mainly in patients on a qualitatively insufficient diet. Also that iron in the proper doses will cure the anaemia even though the worms persist. Further those who suffer from deficiency of iron in their diet are the ones to develop severe anaemia when they become infested with hookworm. On these grounds the suggestion is made to apply the administration of Fe salts in food prophylactically against hookworm anaemia, analogous to the use of iodide in the prevention of goitre. Hitherto the prophylaxis of ankylostomiasis and its associated anaemia has been attained by treatment of patients and the provision and use of latrines.

The end which the authors had in view was more difficult of attainment than the giving of iodide salt for goitre, for several reasons. Thus, the salt of Fe though in considerable quantity must not be such as to make the food unpalatable. The salt must remain stable for the time elapsing between mixing

with the food and partaking of the meal the colour of the food must not be so changed that contamination would be suspected the salt used ought to be haematologically active in small doses and it should be cheap and easily obtainable.

The authors tried 12 different salts of Fe the carbonate phosphate glycerophosphate, the sulphate the scale preparations and others added them to cooking salt to sugar to flour or meal noted the colour of the mixture the taste and the effect of therapeutic doses on the blood. The best was found to be ferrous sulphate mixed with meal or cooking-salt and with the latter of these there was considerable taste detectable so that the most efficient of all was the mixture with flour of manioc or cassava meal. Another good mixture was Ferri et ammon cit with baked beans but this was more difficult in practice because the mixture changed the colour and it had to be very carefully prepared.

The dosage was usually Ferri sulph 1 gm. daily till the haemoglobin reached the normal level of 10-11 gm. per cent the therapeutic period then half this dose 0.5 gm. daily for some 80 days and after that 0.25 gm. for a like period the haemoglobin was thus maintained. Then a vermifuge was given, 3 doses in 26-30 days or 4 doses in 40 days or so and the numbers of worms passed were counted. They might amount to several hundreds (717 in one case). Individual results are presented in graphs and tables.

YANG S. C. H. & LAUBE P. J. Biliary Ascariasis. Report of 19 Cases. *Ann Surgery* 1946 Feb., v 123 No 2 299-303

The authors review some of the literature which records the high incidence of ascariasis in man in China and elsewhere, yet the importance of biliary ascariasis is not sufficiently realized. MUIR [this *Bulletin* 1932 v 29 752] reported on a Chinese subject who had an ascarid in the common bile duct and he quotes 90 cases collected by AVILES [*Surg Gynecol & Obstet* 1918 Nov 459] from the literature up to 1918 and also 12 cases of biliary ascariasis detected at autopsy in the Philippine Islands. MORTON [*Arch. Surgery*, 1928 v 17 324] reported one case from Virginia and eight others in the literature. CH'IN [*Chinese Med. J.* 1933 v 47 1373] reported on a case of acute haemorrhagic pancreatitis due to *Ascaris* impacted in the ampulla of Vater and gave 28 references to biliary and pancreatic ascariasis. CH'IN [this *Bulletin* 1937 v 34 24] reported on a subject with ascariasis of the liver which caused fatal haemorrhage into the biliary tract and thence into the alimentary canal and peritoneal cavity. CHEN [*Chinese Med. J.* 1943 v 61A 51] reported three cases of biliary ascariasis one of which is the first now referred to by the present authors, who report on 19 cases seen in hospitals in Chengtu during the last 3 years.

All the present authors' subjects complained of severe epigastric pain or pain in the right upper quadrant (one subject had pain in the epigastrium and left upper quadrant). The authors consider a distending pain more characteristic of biliary ascariasis than the stabbing kind of pain due to cholelithiasis. All but three of the patients vomited. The general symptoms suggested cholecystitis. Jaundice was present in five all but two had eggs of *Ascaris* in the stools. The temperature was low. Ten of the patients had had similar attacks before. Three of them had cholecystitis four had distended gall bladders and five had tense firm common bile ducts, through the walls of which ascarids could be seen six had dilated bile ducts. Ascarids were present in the common bile duct of all. Typically the anterior one-third

The author notes that the incubation period (at least 12 years) is one of the longest recorded. DIXON and HARGREAVES [this *Bulletin* 1945 v 42 907] reported one of 20 years. of an ascariid 20 cm. long, projected into one of the hepatic ducts, the remaining part of the nematode extending down the common bile duct to the duodenum. In three subjects there were ascariids either partly or completely in the gall bladder as well as in the common bile duct.

The authors comment on the predilection of *Ascaris* to enter any available opening. They have been found projecting through holes in swallowed glass beads or buttons and in the appendix if no openings are available, they burrow into tissues. More serious consideration should be given to biliary ascariasis. If, in an area in which *Ascaris* is endemic, a young person below the usual age for cholelithiasis shows symptoms of disease of the biliary tract, biliary ascariasis should be suspected. This diagnosis is reasonable if the stools contain eggs of *Ascaris* if there is a recent history of ascariasis, if ascariids have been vomited recently if there is a history of similar previous attacks and if the subject has the characteristic peculiar distending pain. ASHBURN L. L. PERRIN T. L. BRADY F. J. & LAWTON A. H. Histologic Changes in Ovary and Uterus of Live *Dirofilaria immitis* recovered from Dogs treated with Trivalent Antimony Compounds. *Arch Pathology* 1945 Nov-Dec v 40 No. 5 334-8 2 figs

We have little knowledge of the effects upon nematodes of drugs used for the treatment of infestations with them. The authors treated dogs infested with *Dirofilaria immitis* with antimonial and mercurial compounds and studied histologically the effects of these drugs upon the ovaries, and upon the developing ova and microfilarial larvae in the uteri of the nematodes.

ITAGAMI and MAKINO [this Bulletin 1927 v 24 995] noted that there were no embryos in the uteri of worms recovered from the heart of one dog eight and a half months after it had been treated with sodium antimonyl tartrate. WRIGHT and UNDERWOOD (*J. et. Med.* 1934 v 29 234) found no embryos in the uteri of adult worms removed from dogs killed after the 37th day of treatment with Fouadin. WRIGHT and HARWOOD [see CHRISTIE, this Bulletin 1944 v 41 139] state that some observations indicate that the sterilization of female *Dirofilaria immitis* was due to fatty degeneration and necrosis of the reproductive cells of the ovary. [They also summarize our knowledge of the mode of action of anthelmintics.] BROWN and SHELDOX (*ibid.* 1942 v 39 190) could not find microfilarial larvae in the uteri of female nematodes recovered alive from dogs treated with a combination of Fouadin and sulphamylamide. LAWTON *et al.* (*ibid.* 1946 v 43 55) report the elimination of circulating microfilarial larvae by 23 out of 24 trivalent antimonial compounds and the failure of mercurial compounds in this respect.

The present authors examined specimens of *D. immitis* recovered from 23 dogs treated with various antimonial compounds and from two dogs treated with mercurial compounds. [No list of these compounds is given.] Microfilarial counts were made from samples of the blood of the dogs each time the drugs were given (6 days a week). As controls 15 female *D. immitis* were used 10 being obtained from five untreated dogs and 5 from two dogs which died 2½ hours after a single dose of one of the drugs being tested. The worms were wound round glass tubing and the ends fixed with rubber bands. They were then fixed in 10% solution of formaldehyde U.S.P. The nematodes were dehydrated in acetone cleared in benzene and cedar oil and embedded in 56°C. paraffin wax. The stains used were haematoxylin azure eosinate [see LILLIE, *Stain Technology* 1941 v 16 1] and van Gieson's stain. All the descriptions given refer to the posterior ovaries anterior ovaries were never

seen. For the details of the appearances seen, the paper and its illustrations must be consulted.

It was evident that at least temporary sterilization of female *Dirofilaria* could be accomplished by treatment of their hosts with antimonial compounds. Eight sterilized *Dirofilaria* were obtained from eight dogs treated with these compounds 70 to 107 days after completion of treatment. Longer observation is required to determine whether the sterilization of *Dirofilaria* is permanent. BROWN [this *Bulletin* 1945 v 42, 53] found that treatment of patients with lithium antimonyl tartrate reduced the microfilarial count 85 to 100 per cent in 4½ to 5 months and thought it likely that the filarial nematodes had been killed. The present authors however think it likely that the nematodes were sterilized for they found females of *Dirofilaria immitis* which were sterilized 3½ months after the end of the treatment. Such a result would be valuable because it would reduce the degree of infestation of the mosquito intermediate hosts. The authors think that although direct action of the drugs on the microfilarial larvae and on multicellular ova may have caused the absence of these developmental stages it is more likely that the drug acted directly on the earlier stages of development so that the microfilarial stage was never reached. The presence of degenerate ova in the uteri of some *Dirofilaria* up to 107 days after treatment of the dogs had ceased is not likely to have been due to persistence of the necrotic material for so long some of these degenerate cells had retained their form which suggests that their degeneration had been recent. The authors therefore suggest that although the ova were shed into the uterus they had been injured so much that they could not develop or that the worms retained the drug so long that the ovaries were influenced by it for some time after treatment ended.

Thus the therapeutic compounds used caused changes in the ovary, the developing ova and microfilarial larvae which agreed well in most instances with the microfilarial counts of the circulating blood. The changes seen were early degeneration or necrosis of the ova and the absence of microfilarial larvae from most of the females. The uteri of some females were entirely empty and there were areas of necrosis in their ovaries. The worms taken from two dogs treated with mercurial compounds were normal. G Lapage

WILLIAMS R. W. & BROWN H. W. The Transmission of *Litomosoides carinii* Filarid Parasite of the Cotton Rat, by the Tropical Rat Mite, *Liponyssus bacoti*. *Science* 1946 Feb 22 224

Cotton rats *Sigmodon hispidus* infected with the filarial worm *Litomosoides carinii* were kept separately in cages in boxes and tropical rat mites *Liponyssus bacoti* were added to infest the rats and multiply on them. Two white rats in separate cages were afterwards placed in the boxes alongside the cages of the cotton rats and became infected with the filaria. Control white rats similarly placed near infected cotton rats but in the absence of the mites did not become infected with the filaria. It was concluded that the tropical rat mite serves as a vector of this worm.

Adult *L. carinii* were found in the pleural cavity of the white rats after 42 and 44 days respectively. In one rat the worms were from 1.165 mm. to 1.2 mm. long in the other rat they were 9 mm. and 42 mm. The control rats were negative when examined at 44 days.

In the infective stage in the mites the worms are from 800µ to 1 000µ in length and it is interesting that a worm only 163µ longer than the biggest worm in a mite was found in the pleural cavity of one of the white rats. This suggests either that the worm reaches the pleural cavity very quickly or that it grows very slowly before reaching the pleural cavity.

Microfilariae were seen in the blood of both cotton and white rats, experimentally infected by mites, after 80 days and it is thought that they may appear as early as 50 or 60 days after exposure to infection. J F Corson

GOLDMAN L. & ORTIZ L. F. Types of Dermatitis in American Onchocerciasis. *Arch. Dermat. & Syph.* 1946 Feb., v 53 No. 2, 79-83 7 figs.

A description of some of the forms of dermatitis found in association with onchocerciasis in Chiapas, Mexico—a district where the endemicity of the disease is high. There are difficulties in deciding what forms are due actually to *Onchocerca* infestation and what to associated conditions, such as pruritus from mycotic infections, pinta, tropical ulcers, syphilis etc.

The authors first give a list of 'cutaneous reactions' observed in patients with onchocerciasis and this includes scarring from cutaneous biopsies or excision of nodules and 'dermatitis from therapeutic agents' neither of which could strictly be called dermatitis in onchocerciasis nor could reactions to the bite of simuliid which might or might not be carrying *Onchocerca*. They then describe in detail three forms of dermatitis definitely associated with onchocerciasis, namely the pigmentation dermatitis or *mal de morado* (purple disease) a lichenoid form, and an eczematoid dermatitis.

In the first of these the skin may be dry or wrinkled, but is usually smooth, of a bluish-red or purple (morado) colour perhaps with local oedema. Biopsy reveals microfilariae in the upper part of the dermis. Most of those with this condition have previously had onchocerca nodules. It may be associated with pruritus and oedema. The face is often involved and puffiness with oedema and cosmophilia are reminiscent of trachinians.

The second or lichen type chiefly affects the face and may occur with the third type (see below) but may also affect the arms and less often the legs. The skin is thickened and hyperpigmented, and there is intense itching. Biopsy reveals microfilariae in the pars papillaris. In the third, the eczematoid type there are papulo-vesicular excoriated lesions sometimes impetiginous or there may be papillomatous verrucose and hyperkeratotic patches on arms, hands and neck.

Treatment of these conditions comprises removal of onchocerca swellings (onchocercomas) and local treatment of the cutaneous condition on the usual lines.

H. Harold Scott.

DEFICIENCY DISEASES.

MUSKELMAN M. M. Nutritional Diseases in Cebu. *War Medicine* Chicago 1945 Nov-Dec, v 8 No 5 325-32.

This is a straightforward account of the experiences of a U.S. army doctor imprisoned by the Japanese in the Philippines. Rations were short during the period of resistance on the Bataan peninsula, and after surrender in April 1942, the ration allowed consisted of about 300 gm. rice, 30 gm. flour, 10 gm. sugar, 10 gm. oil and 100 gm. leaves and stems of vegetables or vines, with occasionally about 5 gm. of carabao meat. This diet provided less than 1,500 calories, less than 30 gm. protein, and very small amounts of vitamins.

Swollen ankles were noted early in many of the men, while some had generalized oedema. Soon 25-50 per cent. had symptoms of beriberi with neuritis and oedema. Signs of pellagra took longer (4-8 months) to appear but then progressed rapidly. A home-grown culture of yeast was prepared in sufficient quantity to ameliorate the symptoms of the worst sufferers, but was insufficient to produce cure.

By late October 1942 90 per cent of the prisoners suffered from malnutrition, and fully 50 per cent were seriously ill with beriberi pellagra malaria, dysentery or other infectious diseases. The fever anorexia, digestive disturbances and diarrhoea associated with these latter diseases contributed to the deficiency states. Symptoms of optic neuritis appeared in over half the prisoners while cerebral spinal and peripheral nerve lesions gave many variations to the clinical picture.

The arrival of Red Cross supplies was followed by an improvement in the diet, and in most cases by a rapid improvement in the physical condition of the prisoners. The ending of these extra supplies was marked by a return to the previous deficiency states again alleviated by a fresh supply while this lasted.

In the summer of 1944 men doing hard labour were issued with food supplying less than 1 000 calories a day while the remainder received less than 800 calories. After this extreme reduction many men were seen to have attacks of hypoglycaemia.

In the autumn of 1944 after a widespread epidemic of dengue about a third of the 500 men in one camp showed a symptom complex similar to myasthenia gravis. Its aetiology and nature were never clearly defined and the condition tended to disappear.

After release of the prisoners from captivity and their return to a full diet, the gain in weight the clearing of pellagrous lesions the loss of oedema and the improvement in the neurological lesions were remarkable. It is felt however that complete recovery is unlikely in patients with advanced nerve lesions.

Scurvy never constituted a serious problem. A long delay in the healing of wounds was an embarrassing surgical problem that may have been determined in part by subclinical scurvy.

H E Harding

MUSSELMAN M M Pellagra in Americans in a Japanese Prison. *Bull U.S. Army Med Dept* 1946 Apr v 5 No. 4 403-11

After 6-7 months on a diet affording less than 1,500 calories less than 30 gm. of protein most of which was of vegetable origin and very small amounts of vitamins pellagra was observed in rapidly increasing numbers of prisoners. Within a short time almost every prisoner showed some signs of the condition while half of them had fairly severe lesions of the mouth and skin. Administration of a thin culture of air borne yeasts was of marked therapeutic value but the quantities available allowed treatment of only the more severe cases.

After the receipt of Red Cross supplies the general condition improved markedly only to relapse with the exhaustion of these supplements. It was noted that pure preparations of vitamins were more effective when the diet was more adequate.

SOUTH AFRICAN RED CROSS SOCIETY (NATAL BRANCH) Report to the Red Cross Society, Natal, on an Experiment with Pre-Digested Protein [DORMER B A.] 20 pp 8 charts & 15 pls

Dr Dormer reports that the death rate from tuberculosis has risen from 250 to 700 per 100 000 in some industrial areas of South Africa during the war and he also finds a great increase in severe oedema in native children and in frank nutritional deficiency diseases in adults. Much of this increase he believes is connected with a lowered standard of nutrition and in particular with a lessened intake of protein.

Colonel Watkins Pitchford has worked out a method of enzymic digestion of whale flesh that produces stable concentrations of amino acids or mixtures

Microfilariae were seen in the blood of both cotton and white rats, experimentally infected by mites after 80 days and it is thought that they may appear as early as 50 or 60 days after exposure to infection. *J F Corson*

GOLDMAN L. & ORTIZ L. F. Types of Dermatitis in American Onchocerciasis. *Arch. Dermat. & Syph.* 1946 Feb., v 53, No. 2, 79-83 7 figs.

A description of some of the forms of dermatitis found in association with onchocerciasis in Chiapas Mexico a district where the endemicity of the disease is high. There are difficulties in deciding what forms are due actually to *Onchocerca* infestation and what to associated conditions, such as pruritus from mycotic infections, pinta, tropical ulcers, syphilis etc.

The authors first give a list of cutaneous reactions observed in patients with onchocerciasis and this includes "scarring from cutaneous biopsies or excision of nodules and dermatitis from therapeutic agents neither of which could strictly be called dermatitis in onchocerciasis, nor could "reactions to the bite of simuliid which might or might not be carrying *Onchocerca*. They then describe in detail three forms of dermatitis definitely associated with onchocerciasis, namely the pigmentation dermatitis or *mal de morado* (purple disease) a lichenoid form, and an eczematoid dermatitis.

In the first of these the skin may be dry or wrinkled, but is usually smooth, of a bluish-red or purple (morado) colour perhaps with local oedema. Biopsy reveals microfilariae in the upper part of the dermis. Most of those with this condition have previously had onchocerca nodules. It may be associated with pruritus and oedema. The face is often involved and puffiness with oedema and eosinophilia are reminiscent of trichinosis.

The second or lichen type chiefly affects the face and may occur with the third type (see below) but may also affect the arms and, less often, the legs. The skin is thickened and hyperpigmented, and there is intense itching. Biopsy reveals microfilariae in the pars papillaris. In the third, the eczema told type there are papulo-vesicular excoriated lesions, sometimes impetiginous or there may be papillomatous verrucose and hyperkeratotic patches on arms, hands and neck.

Treatment of these conditions comprises removal of onchocerca swellings (onchocercomas) and local treatment of the cutaneous condition on the usual lines.

DEFICIENCY DISEASES.

MUSSELMAN M. M. Nutritional Diseases in Cebu. *War Medicine* Chicago 1945 Nov-Dec. v 8, No. 5 323-32.

This is a straightforward account of the experiences of a U.S. army doctor imprisoned by the Japanese in the Philippines. Rations were short during the period of resistance on the Bataan peninsula, and after surrender in April 1942, the ration allowed consisted of about 300 gm. rice 30 gm. flour 10 gm. sugar 10 gm. oil and 100 gm. leaves and stems of vegetables or vines, with occasionally about 5 gm. of carabao meat. This diet provided less than 1,500 calories, less than 30 gm. protein, and very small amounts of vitamins.

Swollen ankles were noted early in many of the men, while some had generalized oedema soon 25-50 per cent. had symptoms of beriberi with neuritis and oedema. Signs of pellagra took longer (4-8 months) to appear but then progressed rapidly. A home-grown culture of yeast was prepared in sufficient quantity to ameliorate the symptoms of the worst sufferers, but was insufficient to produce cure.

By late October 1942 90 per cent of the prisoners suffered from malnutrition, and fully 50 per cent were seriously ill with beriberi pellagra malaria, dysentery or other infectious diseases. The fever anorexia, digestive disturbances and diarrhoea associated with these latter diseases contributed to the deficiency states. Symptoms of optic neuritis appeared in over half the prisoners while cerebral spinal and peripheral nerve lesions gave many variations to the clinical picture.

The arrival of Red Cross supplies was followed by an improvement in the diet, and in most cases by a rapid improvement in the physical condition of the prisoners. The ending of these extra supplies was marked by a return to the previous deficiency states again alleviated by a fresh supply while this lasted.

In the summer of 1944 men doing hard labour were issued with food supplying less than 1 000 calories a day while the remainder received less than 800 calories. After this extreme reduction many men were seen to have attacks of hypoglycaemia.

In the autumn of 1944 after a widespread epidemic of dengue about a third of the 500 men in one camp showed a symptom complex similar to myasthenia gravis. Its aetiology and nature were never clearly defined and the condition tended to disappear.

After release of the prisoners from captivity and their return to a full diet the gain in weight the clearing of pellagrous lesions the loss of oedema and the improvement in the neurological lesions were remarkable. It is felt however that complete recovery is unlikely in patients with advanced nerve lesions.

Scurvy never constituted a serious problem. A long delay in the healing of wounds was an embarrassing surgical problem that may have been determined in part by subclinical scurvy.

SOUTH AFRICAN RED CROSS SOCIETY (NATAL BRANCH) Report to the Red Cross Society, Natal, on an Experiment with Pre-Digested Protein [DORMER, B A] 20 pp 8 charts & 15 pls

Dr Dormer reports that the death rate from tuberculosis has risen from 250 to 700 per 100 000 in some industrial areas of South Africa during the war and he also finds a great increase in severe oedema in native children, and in frank nutritional deficiency diseases in adults. Much of this increase he believes is connected with a lowered standard of nutrition and in particular with a lessened intake of protein.

Colonel Watkins Pitchford has worked out a method of enzymic digestion of whale flesh that produces stable concentrations of amino acids or mixtures

of these acids with polypeptides, peptones, etc. Whale flesh is commonly almost completely wasted and large amounts of it could be made available in this manner. The products are bitter and unpalatable but their taste can be disguised in soups, wines, chocolates, toffees and biscuits.

Experimental trials of these products have given very favourable impressions to their users. Patients with pulmonary tuberculosis who were previously losing weight steadily, have in most cases gained weight, and their general condition has improved. Similar results have been obtained in a few patients with tuberculous enteritis. It is not claimed that feeding with these mixtures is a cure for tuberculosis, but the improvement produced in the patient's condition sometimes allows active therapy to be undertaken.

Native children suffering from malignant oedema or infantile pellagra have shown rapid improvement when treatment is started with these products and glucose. Tropical ulcers have been found to heal rapidly. Feeding with these protein digests is also recommended for patients with peptic ulcers, nephrosis, hepatitis, diabetes, hyperthyroidism, anorexia nervosa, and various allergic states.

[This is a report to the South African Red Cross Society urging an extension of the support given to Colonel Watkins Pitchford. It is not meant to be a properly documented scientific report. Judged, however, on the very lowest level it does draw attention to the very serious effects of malnutrition in South Africa, and it points to a hitherto untapped source of protein.]

GILLMAN J. MANDELSTAM, J. & GILLMAN T. A Comparison of Chemical and Histological Estimations of the Iron and Copper Content of the Livers of Africans in relation to the Pathogenesis of Cytochromosis and Cirrhosis (Haemochromatosis). *South African J. Med. Sci.* 1945 Dec. v 10 No. 4 109-36 7 figs. on 1 pl. [80 refs.]

A comparison of the amount of iron assessed by histological methods and that found by chemical analysis in 73 livers showed fairly good correlation. It was found that iron might be visible histologically without any increase in the quantity found chemically i.e. that normally bound and invisible iron could become visible. Livers from pellagras were classified in four types [GILLMAN and GILLMAN this *Bulletin* 1946 v 43 364]. On the whole this typing was found to correspond with increasing quantities of iron determined chemically but there was considerable overlap between individual livers in each group.

Cirrhosis and pigmentation are separate conditions. Extensive cirrhosis may exist without a significant increase in the amount of iron. Iron may be present in quantities as great as those described in haemochromatosis without any cirrhosis. Cirrhosis may be found with very varying quantities of iron which may be in liver cells only or in the portal tracts as well.

The amount of copper in the liver does not vary directly with the amount of iron. In a marked increase in the latter there is usually an increase in

followed by a summary
changes in pigs given a

diet deficient in thiamin. In these animals thiamin deficiency leads to severe changes in cardiac function, and produces well defined histological lesions. It is still undecided whether a deficiency of thiamin produces similar changes in man. The lesions found in pigs are unlike those that have been described as occurring in the heart in beriberi and resemble more those that have been described under the title of isolated myocarditis or Fiedler's myocarditis.

SPRUE.

BLACK D A K. FOURMAN L P R. & TRINDER, P. Fat-Absorption in Tropical Sprue. *Lancet* 1946 Apr 20 574-5

[A piece of work of no little importance to those interested in the study of the problems of sprue.] The authors have carried out experiments to determine the degree of fat-absorption in sprue at an early stage. All the patients suffered from steatorrhoea and had lost weight some had glossitis and showed signs of macrocytic anaemia. The percentage of fat-absorption was determined by the formula

$$\frac{(\text{Dietary fat} - \text{excreted fat}) \times 100}{\text{Dietary fat}}$$

In untreated patients with sprue in various stages but with formed stools the absorption ranged between 51 and 85 per cent., with an average of 75.8 per cent. three others with watery diarrhoea, had generally a lower absorption 30.55 and 64 per cent. In the cases of five patients the fat content of the diet was raised by about 40 per cent. from 69 to 96 gm. a day. As a result more fat was excreted but there was little change in the proportion absorbed in two it remained practically the same (82 and 85 in place of 83 and 87 per cent.) in one it rose slightly (83 to 88) in two it fell (from 80 and 51 to 74 and 44 respectively). The natural inference is that moderate increase in dietary fat has little effect on absorption.

Giving nicotinic acid, riboflavin or pantothenic acid did not improve the absorption. The effect of liver is more remarkable though the stomatitis and glossitis improved and weight was gained fat absorption was not affected unless there was diarrhoea in such patients improvement of the diarrhoea was accompanied by increased fat-absorption. Giving of a yeast extract of the Marmite type seemed to increase fat-absorption this may be due to its folic acid content. The question is to be the subject of further study.

From the investigations so far carried out the following points emerge (1) Intestinal secretion of fat does not play an important part in causing steatorrhoea for the latter disappears on a very low fat diet. (2) Sprue is not due to diminished motility of the villi or reduced absorptive surface because the absorption percentage remains almost constant when the intake of fat is moderately increased. (3) This constancy is more easily explained by theories based on the failure of an enzyme system such as that concerned in phosphorylation. [See STANNUS this *Bulletin* 1943 v 40 259]

WESTROBE M. M. Relation of Nutritional Deficiency to Cardiac Dysfunction. *Arch. Intern. Med.* 1945 Nov-Dec. v 76, No. 5 341-6. [Refs. in footnotes.]

A brief review of the literature on cardiac beriberi is followed by a summary of the work at the University of Utah on the cardiac changes in pigs given a

cent whereas among 30 Mongoloid and 120 Caucasoid individuals no example of sicklaemia was found

In 58 sicklaemic persons with morbid conditions producing circulatory stasis anatomico-pathological changes of sickle cell anaemia were not observed. These findings contradict the hypothesis that stasis is a sufficient factor for the transition from a sicklaemic to an anaemic condition. In 13 sicklaemic persons infected with malaria no symptoms of sickle cell anaemia were observed, but it was also verified that parasitism by *P. vivax* does not check sickling.

It is important when determining sicklaemic indices to take into consideration the direct hereditary factor as the index for a familial group may be much larger than that obtained by random sampling to differentiate the familial incidence the term familial sicklaemia index is suggested. Sickle cell anaemia may only be obvious at times in generations very distant one from another giving rise to a skipping phenomenon in such cases the condition is maintained in the intervals through sicklaemic individuals who may be regarded as potentially diseased or as healthy carriers of a pathogenic feature.

The systematic and periodical examination of sicklaemic individuals is urged as such investigations may throw light on the genetically transmitted factors and also on the intrinsic and extrinsic factors associated with the disease. Control of the condition would also be aided by a census of sicklaemic individuals and remarks on their identification cards by the systematic examination for sicklaemia of all the newly born by the supervision of all sicklaemic individuals who should be required to present themselves to the public health authorities periodically and especially on the appearance of any symptoms of the disease and finally by the inclusion of tests for sicklaemia in prenuptial medical examinations.

F Murgatroyd

VENOMS AND ANTIVENENES

MARTIN W B Clinical Experience with Snake Bites on Okinawa. *Bull U.S. Army Med Dept* 1946 Jan v 5 No 1 79-82

Nine cases of snake bite which occurred during the Okinawa campaign are described. Four case reports are given in full. In all instances in which the snake was identified it was the Habu (*Trimeresurus flavocinctus*). There were no fatalities. Clinically there was a rapid onset of symptoms with brief local anaesthesia in some cases followed by pain and swelling and systemic disturbance. The venom was mainly haemotoxic and had no effect on the brain centres.

Treatment recommended includes criss-cross incisions over the site of the fang marks suction immediately and intermittently for 12 hours and if the bite is in a limb the application of a tourniquet tight enough to prevent venous return but not enough to compress the arteries and it should be released every 20 minutes and replaced at higher levels if the swelling is progressing proximally. The authors advise the administration of Nearctic antivenene although none of their cases was treated in this way. Penicillin should be given in doses of 20 000 units 3-hourly (after an initial dose of 30 000 units) in view of the penetrating wound and local oedema.

[No mention is made of washing the site before the incision in order to remove ejected venom.]

B G Macgrath

Crystalline synthetic *L. casei* factor was dissolved in water with a small quantity of disodium phosphate, and the solution was autoclaved 15 mgm. of the factor in this solution were injected intramuscularly daily. Improvement both clinical and haematological followed rapidly in all three patients: the symptoms of glossitis disappeared within 3 or 4 days and the lingual papillae were regenerated; the diarrhoea ceased, the appetite improved and the body weight increased, one patient gaining 26 lb in the first 6 weeks. There was a great increase in the numbers of reticulocytes, blood platelets and blood leucocytes, and some increase also of haemoglobin and of erythrocytes: sternal puncture showed improvement in the bone marrow.

This striking response to the treatment suggested to the authors certain possible relationships: the synthetic *L. casei* factor is probably identical with, or closely related to, the substance in liver extract which is effective in the treatment of sprue, this syndrome and that of vitamin M deficiency in the monkey being similar (LANGSTON *et al* *J Exper Med* 1938, v 68, 923) since the factor which relieves the macrocytic anaemia of pregnancy is closely allied to vitamin M, the synthetic *L. casei* factor may be efficacious in the treatment of that form of anaemia: the *L. casei* factor may be related to the erythrocyte maturing factor since in sprue and pernicious anaemia the blood picture, the bone marrow and the glossitis are similar.

SPIES *et al* (this *Bulletin* 1946 v 43 375) found that synthetic *L. casei* factor was effective in the treatment of incompletely diagnosed macrocytic anaemia and GOLDSMITH (personal communication) reported the successful treatment of "nutritional macrocytic anaemia with folic acid".

The authors' references include also DAY (in *Vitamins and Hormones* ed. by HARRIS and THIMANN 1944 New York, Acad Press Inc v 2, 71) WILLS and STEWART [*Bulletin of Hygiene* 1936 v 11 136] [Other references to macrocytic anaemia are: this *Bulletin* 1938 v 35 846 1939 v 36 422 1940 v 37 863-5 1941 v 38, 184 1942 v 39 482, 483 1943 v 40 405 484 838 1945 v 42, 59 222, 308, 482 1946 v 43 146.]

HAEMATOLOGY

DA SILVA E. M. Estudos sobre índice de sicklaemia [Studies on the Sicklaemia Index.] *Mem Inst Oswaldo Cruz* 1945 Apr v 42 No 2 315-40 10 figs [47 refs.] English summary

The sickle cell trait may be detected by several well-known methods. For a rapid determination, the blood may be exposed to a current of carbon dioxide. For large scale surveys coverglass preparations of either fresh blood or blood mixed with an isotonic anticoagulant solution are useful. The addition of anti-A or anti-B agglutinating serum does not check sickling so that by such combinations the blood group and the sickle cell trait may be determined at the same time. Similarly, the addition of solutions of brilliant cresyl blue may be used for the simultaneous determination of the degree of reticulocytosis and the sicklaemia. For the study of the process of sickling mixtures of blood and isotonic anticoagulant may be sealed in tubes and sampled at intervals, the cells being fixed by the addition of formalin at the time of sampling. Finally, maceration in isotonic saline or fixative solutions, of tissues preserved in alcohol or formalin, may enable a retrospective determination of sicklaemia to be made after a period as long even as 26 years.

Among a heterogeneous group of 1130 negroes and negro cross-breeds 113 sicklaemic individuals were found, giving an index of approximately 10 per

increasing prostration and death in 3 to 40 hours. With guineapigs large doses to 165 gm. subcutaneously were needed to produce these symptoms and a local saccular oedema occurred. 80 mgm. intramuscularly caused redness and swelling but was not fatal. In rabbits 50 mgm. intravenously caused death in 15 minutes. In pigeons 6-8 mgm. intravenously killed in 10 minutes or less but as much as 125 mgm. were needed intramuscularly or subcutaneously to kill in 10 minutes by the former route in 4-12 hours by the latter.

Opisthophthalmus venom. 2-3 mgm. were needed intravenously to kill mice in 1-20 minutes the symptoms of excitability, dyspnoea and paralysis resembling those with the other venoms. Subcutaneous and intramuscular injections in doses of 20-80 mgm. in guineapigs differed from the other venoms in producing severe local haemorrhagic swelling, gelatinous oedema and later sloughing the same occurred in pigeons. These routes were not tried with rabbits.

As regards haemolysis this effect occurred with all the venoms but only in relatively high concentrations such as 20 mgm. per cc. guineapig erythrocytes were haemolysed more readily than sheep's cells and the haemolysis was less marked with *Parabuthus* venom than with either of the others.

The effects of heat were observed, at 70°C in a water-bath for $\frac{1}{2}$ hour at boiling point for 30 minutes and for 90 minutes the toxicity of the venoms remained practically unchanged. In high concentration of 10-30 mgm. per cc. the *Parabuthus* venom had a graded proteolytic action on gelatin *in vitro* the other two had no such action.

Tests with antivenenes of *Naja flava* and *Buthus ardens* showed them to be ineffectual against these scorpion venoms. Preparation of specific antiscorpion serum from horses was undertaken starting with toxoid and continuing with natural venom. Practitioners were asked to report on the results of the use of these antivenenes and so far though only a few reports have come in, they appear to be favourable when the serum is injected intramuscularly in a dose of 10 cc.

TINKHAM E. R. A Poison-Squirting Spider *Bull. U.S. Army Med. Dept.*
1946 Mar. v 5 No 3 361-2.

A soldier in Florida, U.S.A. while inspecting the tail lamp of his motor cycle one day at noon, saw a spider about 12 to 15 in. distant and disturbed it. At that moment he felt something enter his eye and it caused him great pain. His eye became inflamed, conjunctivitis persisting for two days. He thought the spider had squirted something from its mouth into his eye, while another soldier who was present thought it had squirted from its abdomen. The spider was caught and was identified as *Peucedania viridans* the identification being confirmed afterwards from the author's drawings and description, by H. J. GERTSCH arachnologist American Museum of Natural History New York who however stated that this species was not known to squirt venom and that he knew of no other spider with that reputation except perhaps *Scytodes* which captures its prey by spitting on it from a short distance.

GRASSET, E. SCHAAFSMA, A. & HODGSON, J. A. Studies on the Venom of South African Scorpions (*Parabuthus Hadogenes Opisthophthalmus*) and the Preparation of a Specific Anti-Scorpion Serum. *Trans Roy Soc Trop Med & Hyg* 1946 Apr v 39 No 5 397-421 3 figs. on 2 pls. [19 refs.]

In South Africa, cases of scorpion sting are not infrequent but, as elsewhere where scorpions abound, fatalities are rare and occur mostly in children. Much work has been done on the taxonomy and systematics of South African scorpions but little on their relative toxicity. The authors in this paper record their investigations on three genera *Parabuthus* especially *P. transvaalicus* and *P. irradians* from the northern Transvaal and Bechuanaland; this genus is common throughout Africa and Arabia but is not found in Natal and Pondoland. *Hadogenes* especially *H. troglodytes dentatus* found in South Africa, Portuguese East Africa, the Congo and Madagascar but not along the coast from Capetown to Port Elizabeth. *Opisthophthalmus* especially *O. walberghii* and *O. glabrifrons* from Bechuanaland.

For experiment venom was obtained from *Parabuthus* by aspiration with a pipette after the tip of the telson had been cut from the others, which had more delicate telsons, by squeezing out with forceps. In each case, the venom, a white milky fluid, was collected on a watch-glass and allowed to dry. The average yields of dried venom for each scorpion were *Parabuthus* 4.8 mgm. *Hadogenes* 2.7 mgm. *Opisthophthalmus* 1.4 mgm.

For their experiments the authors prepared saline solutions standardized to contain 10 mgm. per cc. and the animals used were mice, guinea-pigs, rabbits and pigeons. Injections were made intravenously, subcutaneously, intramuscularly, intracutaneously and intracerebrally. In solution the venoms are unstable, so all experiments were made with freshly prepared solutions. The results were as follows —

Parabuthus venom. White mice average weight 22 gm. 0.1-0.4 mgm. intravenously caused immediate dyspnoea, staggering and inco-ordination, extension of hind legs, or gasping uncontrolled jumping and paralysis; death occurred in $\frac{1}{2}$ to 5 minutes with progressive paralysis and asphyxia. Subcutaneously the symptoms were similar but the dose needed was four times the intravenous dose. 0.002-0.1 mgm. intracerebrally produced immediate convulsions, trembling, paralysis and death in a few seconds with the larger dose. In other animals the symptoms were similar: the dosage for guinea-pigs of 350-400 gm. was 1-2 mgm. subcutaneously or intramuscularly; for rabbits of 2,000 gm. 5 mgm. intravenously; in pigeons of 400-450 gm., with 0.8-1.5 mgm. intravenously there were marked neuromotor symptoms. To epitomize *Parabuthus* venom is neurotoxic producing at first neuromuscular excitability and dyspnoea from action on the respiratory centre, followed by paralysis and asphyxia.

Hadogenes venom. 0.4-0.6 mgm. intravenously in mice caused dyspnoea and paralysis, and death within 15 minutes. Subcutaneously large doses, up to 40 mgm., produced hyperexcitability for 1-2 hours, then trembling and

increasing prostration and death in 3 to 40 hours. With guineapigs large doses to 185 gm subcutaneously were needed to produce these symptoms and a local saccular oedema occurred. 80 mgm. intramuscularly caused redness and swelling but was not fatal. In rabbits 50 mgm. intravenously caused death in 15 minutes. In pigeons 6-8 mgm. intravenously killed in 10 minutes or less, but as much as 125 mgm. were needed intramuscularly or subcutaneously to kill in 10 minutes by the former route in 4-12 hours by the latter.

Opisthophthalmus venom. 2-3 mgm. were needed intravenously to kill mice in 1-20 minutes the symptoms of excitability, dyspnoea and paralysis resembling those with the other venoms. Subcutaneous and intramuscular injections in doses of 20-80 mgm. in guineapigs differed from the other venoms in producing severe local haemorrhagic swelling, gelatinous oedema and later sloughing the same occurred in pigeons. These routes were not tried with rabbits.

As regards haemolysis this effect occurred with all the venoms but only in relatively high concentrations such as 20 mgm. per cc. guineapig erythrocytes were haemolysed more readily than sheep's cells and the haemolysis was less marked with *Parabuthus* venom than with either of the others.

The effects of heat were observed at 70 C. in a water-bath for $\frac{1}{2}$ hour at boiling point for 30 minutes and for 90 minutes the toxicity of the venoms remained practically unchanged. In high concentration of 10-30 mgm per cc. the *Parabuthus* venom had a graded proteolytic action on gelatin *in vitro* the other two had no such action.

Tests with antivenenes of *Naja flava* and *Bilis arctans* showed them to be ineffectual against these scorpion venoms. Preparation of specific antiscorpion serum from horses was undertaken starting with toxoid and continuing with natural venom. Practitioners were asked to report on the results of the use of these antivenenes and so far though only a few reports have come in they appear to be favourable when the serum is injected intramuscularly in a dose of 10 cc.

TINKHAM E. R. A Poison-Squirting Spider *Bull U.S Army Med Dept*
1946 Mar v 5 No 3 361-2

A soldier in Florida, U.S.A. while inspecting the tail lamp of his motor cycle one day at noon, saw a spider about 12 to 15 in. distant and disturbed it. At that moment he felt something enter his eye and it caused him great pain. His eye became inflamed conjunctivitis persisting for two days. He thought the spider had squirted something from its mouth into his eye, while another soldier who was present thought it had squirted from its abdomen. The spider was caught and was identified as *Peucea viridans* the identification being confirmed afterwards from the author's drawings and description by H. J. GERTSCH, arachnologist American Museum of Natural History New York, who however stated that this species was not known to squirt venom and that he knew of no other spider with that reputation except perhaps *Scytodes* which captures its prey by spitting on it from a short distance.

DERMATOLOGY AND FUNGUS DISEASES

VARELA, G. Estudios serológicos y cardiovasculares de un grupo seleccionado de enfermos de mal del pinto. [Serological and Cardiovascular Studies on Pinta Patients.] *Rev. Inst. Salubridad y Enfermedades Trop. Mexico*. 1945 Sept., v 6 No 3 163-6.

Twenty-nine patients suffering from mal del pinto whose ages ranged between 4 and 20 years were selected because they had not received any treatment for their disease and gave no history of having been infected with syphilis. Tests were made with their sera and cerebrospinal fluids for complement fixation, and the reactions of Pandy, Nonne-Apel't and Mazzini were carried out with the cerebrospinal fluids. Radiograms were taken of the heart and electrocardiograms made.

Some previous investigators have recorded positive results with the c.s.f. for example, the Mexican Commission on Pinta in 1930 (number of cases not stated) reported Wassermann reactions markedly positive. PARDO CASTELLO in 1936 recorded 4 out of 26 as having an increase in globulin and one with a positive Wassermann reaction and positive Kahn. GRAU and TRIANA in 1937 recorded two positive out of 12. On the other hand, BOTERO in 1939 and León BLANCO in 1942 found no change in the fluid of 69 and 53 patients respectively. The present author's investigations support the last named. The sera in all his patients gave a marked positive reaction but the cerebrospinal fluids were without exception negative. The electrocardiograms also showed no departure from the normal though three showed by X rays an increased area of the aorta.

DOBES W. L. & JONES J. Erythema Streptogenes. *Arch. Dermat. & Syph.* 1946 Feb., v 53 No. 2 107-14 4 figs. [12 refs.]

Dermatoses associated with streptococci are common but the condition described in this paper does not appear to have found a place in the text books. It is a dry dermatitis, seen in Europeans as well as natives, but more often in the latter and in children in the authors experience. The eruption may appear anywhere but is most common on the face. There is first an erythema which fades in a week or two when a scalliness is seen and depigmentation sets in, and in 2-3 months there is a depigmented patch, with ill-defined border (thus differing from the more marked and sharply defined areas of vitiligo) the affected areas are smooth or show a fine branny desquamation. Scrapings from the lesions were taken from seven patients. In two cases there was no growth though repeated attempts were made the condition had existed for 8 months in one and 12 months in the other and may have been receding. In the other five haemolytic streptococci were isolated (in one case together with a haemolytic *Staphylococcus aureus*) the duration of these positive cases ranged between 3 and 18 months. The best treatment is local rubbing in of a crude tar ointment pigmentation usually returns in about 3 months. That the condition is actually caused by the streptococcus is not proved but it is maintained that streptococci on the normal skin of persons in good health can never be considered as saprophytic.

BADHWAR, R. L. NAYAR, S. L. & CHOPRA, I. C. Indian Plants liable to produce Dermatitis. *Indian J. Agric. Sci.* 1945 June, v 15 Pt. 3 155-71 [16 refs.]

In India some 76 plants are known to produce irritation of the skin and even actual dermatitis in certain persons all are not equally susceptible. The

mode of action differs. Plants causing direct mechanical injury as by penetration of spines and thorns wounds from which may subsequently become infected and so set up dermatitis are excluded from this article. Included are —

(1) Those of the *Rhus* type and allied genera whose sap exudes when the plant is injured contact with the sap sets up a dermatitis due to a phenolic oily resin which it contains and which is known as toxicodendrol. It is not itself volatile but it may be conveyed in the soot of burning plants and also by insects which have alighted on an injured plant. Claim has been made that it is present in the pollen but say the authors this is not so. The irritation may be relieved by alkaline applications and a brief immunity can be produced by subcutaneous injection of an alcoholic extract but this immunity is very transient not lasting for more than a month.

(2) A second type of irritant is the *Urtica* type nettles are examples and the most potent of these in India is *Laportea cranulata* the Fever nettle or Devil nettle. When the fragile hairs of the nettle penetrate the skin they break and the irritant in the hair enters the tissue. The protoplasm of the hairs is alkaline but encloses an acid cell sap which contains formic acetic butyric and other volatile fatty acids.

(3) A third group comprises plants which when ingested produce photosensitization and consequent dermatitis of unpigmented parts. Examples of this group are *Fagopyrum esculentum* and *Hypericum perforatum*.

Lastly there is (4) a miscellaneous group e.g. *Xanthium strumarium* which produces dermatitis in a few who happen to be sensitive to it the toxic principles are still undetermined. In others e.g. *Erigeron canadensis* there is an irritating essential oil. In *Podophyllum hexandrum* it is a resin in the root stock which is the irritant in other cases the mechanism is not known dust from dried plants may irritate the nasal and ocular mucosa.

The authors present in a table a list of the 76 plants known in India to cause dermatitis they give also the English and vernacular names their geographical distribution the part of the plant responsible for causing the dermatitis and where known, the toxic principle in each case. [A valuable piece of work.]

MENDELSON H V Lemon Grass Oil a Primary Irritant and Sensitizing Agent. *Arch. Dermat. & Syph.* 1946 Feb v 53 No 2 94-8.

On the publication of his report of eight cases of dermatitis venenata due to lemon grass oil [see this *Bulletin* 1945 v 42 66] the author received samples of the oil from three sources one from Florida containing 75 per cent of citral an aldehyde constituent of the oil another from India also containing 75 per cent and a third from Guatemala with 76.2 per cent. He also received three samples of ionones in which the aldehyde is converted into a ketone. They are highly aromatic and are used in making perfumes and cosmetics.

The author made patch tests with all of these on 15 persons. All reacted with vesicles and bullae to the undiluted oils indicating a direct irritant action. dilution of the oil 1 in 10 or more, might result in a delayed reaction after 6 days indicative of induced sensitivity i.e. the diluted forms acted as sensitizers and when the patients were tested again 3 weeks later with the diluted oils erythema and vesiculation were observed on removal of the test patches after 48 hours application. In no instance was there any reaction to the ionones.

H Harold Scott

NUÑEZ ANDRADE, R. Dermatitis causada por *Haematosiphon inodora* (Duges, 1892) [Dermatitis due to *H. inodora*] *Medicina*, Mexico 1946 Feb 10 v 26 No. 501 45-51 4 figs. English summary

"1 The author reports 21 cases in residents in Mexico City of a type of Dermatitis caused by bites of the chicken-bug called *Haematosiphon inodora* (Duges, 1892)

"2 One of the cases had been diagnosed as urticaria by food allergy another as Prurigo mitis, and the rest of them were considered as bites from bedbugs (*Cimex lectularius*)

"3 The dermatitis caused by the *Haematosiphon inodora*, was generally observed in all the inhabitants of the infected houses and furthermore almost all the houses in the same quarter were infested by the insects.

4 This dermatitis is polymorphous, having the appearance of hives [a popular name for urticaria and other skin diseases] papules vesicules venocapustules, scratches or scars

5 This dermatitis causes intense itching, burning sensations pain and sometimes general malaise and a rise of temperature derived from secondary infections."

PEASNER, E. F. Coccioidomycosis at U.S.M.C. Air Station, Mohave, California. *U.S. Nav Med Bull.* 1946 Feb., v 46 No 2, 229-36

In view of the discovery of isolated cases of coccioidomycosis at a Naval Air Station at Mohave, California, an investigation was made into the possibility of the station being situated in an endemic area of the disease. All the staff were subjected to the coccioidin skin test as soon as possible after arrival at the station, and those on whom the result of the test was negative were tested again after an interval of about 4½ months. If the second test had a positive result it was assumed that infection had occurred in the interval between the tests. Twenty three men who were found negative by the first test gave positive reactions at the second test and none of these had been exposed to infection outside the station in the interval. In addition to these 23 seven men who were coccioidin negative on arrival at the station were admitted to hospital at some later time for an illness which was diagnosed as coccioidomycosis and all seven became sensitive to coccioidin during their illness. Clinical descriptions are given of these seven cases.

As none of the 30 men referred to had visited any known endemic focus of coccioidomycosis outside the station it was concluded that the infections must have occurred at the Mohave Air Station and that the vicinity of the station is an endemic area of coccioidomycosis.

TWIDING, H. E., DIXON, H. M. & WEIDMAN, F. D. Penicillin in Treatment of Madura Foot. Report of Two Cases. *U.S. Nav Med Bull.* 1946 Mar., v 46 No 3 417-29 8 figs. [10 refs.]

The authors describe two cases of mycetoma—one caused by *Monosporium apiospermum* and the other by a newly-named fungus *Cephalosporium granulomatus* n.sp. Weidman and Kligman. In the first case the disease was of 7 years duration and some of the bones of the tarsus and metatarsus were involved. Penicillin treatment was instituted and this resulted in considerable improvement in the condition of the foot, although new lesions continued to appear. After a total dosage of 3,700,000 units, the patient was discharged with a prognosis of possible cure. Relapse occurred, however, and, after a further course of 2,100,000 units of penicillin had been given ineffectually the diseased foot

was amputated. In the second case the disease was of only two years duration and was limited to the soft tissues of the foot. Penicillin was given in doses of 20 000 units every three hours until a total of 2,300 000 units had been given. Improvement was rapid and apparently permanent and the patient was discharged from hospital six weeks after the conclusion of the penicillin treatment.

HEAT STROKE AND ALLIED CONDITIONS.

SHELLEY W B & HORVATH S M The Oral and Rectal Temperatures in Hot Environments. *Bull U.S Army Med Dept* 1946 Apr v 5 No 4 459-61 1 fig

A comparison of rectal and oral temperatures of men working in a very hot room (120°F 36 per cent R H) environment showed the rectal temperature to range from 1.4°F below to 3.9°F above oral temperature averaging 1.2°F higher than the oral

LADELL W S S Changes in the Chloride Concentration of Sweat with Acclimatization. *Biochem J* 1945 v 39 No 5 xlvii-xlviii.

The chloride concentration in serial sweat samples from the arms of subjects working in a hot humid environment rises as the exposure continues. Sweat is always hypotonic and the glands therefore must do work when they excrete sweat less work is done if the sweat is more concentrated, and the phenomenon reported may therefore be a manifestation of fatigue. Total salt loss is practically constant in a given individual from day to day for a given total of sweat lost so long as the rate of sweating remains the same. In rapid acclimatization there is no fall in sweat chloride concentration.

One subject lived in a hot room day and night and after the first few days the chloride concentration of his sweat no longer rose with time this was not due to salt lack. After the subject had left the hot room he lost this acclimatization effect. Other subjects who were exposed to heat for some hours every day over a period of many months showed the same effect but less markedly. Salt loss for heavy sweating became less showing diminished capability of the sweat glands to fatigue. This diminution in salt loss from sweat which occurs in hyper acclimatization should not be confused with the fall in chloride concentration in sweat which occurs as a result of deficiency of salt intake.

LUCKIESH M TAYLOR A H COLE H. N & SOLLMANN T Protective Skin Coatings for the Prevention of Sunburn. *J Amer Med Ass* 1946 Jan. 5 v 130 No 1 1-6

This is an account of researches undertaken in December 1942 for the U.S Army Air Force to provide an effective protective substance for the prophylaxis of sunburn. It was a collaboration between two physicists Luckiesh and Taylor and two physicians Cole and Sollman. From previous observations on the ultra violet absorbing power of different substances it was decided

to concentrate only on preparations and mixtures containing any of the following: titanium dioxide, salicylates, zinc oxide, and petrolatum jelly. Various mixtures of two or more of these were tested, including several proprietary preparations. Several different varieties of petrolatum jelly without anything added were also tried. Physical tests showed almost complete absorption of ultra violet radiation by 0.03 mm. of a phenyl salicylate and petrolatum flavum mixture with or without added zinc oxide. Dark red vet. petrolatum was also selectively opaque to the erythema spectrum. Titanium dioxide was not so effective. For a biological test small areas of skin covered with the material being tested were exposed for varying periods to high intensity radiation and any development of erythema was noted without a protective coating on the skin. Erythema was usually produced with about 15 seconds exposure. It was found that zinc oxide diminished the protective power of the salicylate petrolatum mixtures, and that the dark red petrolatum gave complete protection for exposures of 20 minutes.

A factor of practical importance was resistance to washing, as the preparation was to be used by aviators who might be brought down into the sea. Poor resistance to washing eliminated preparations with a cold cream basis. Resistance to freezing was also necessary as the petrolatum would be carried in aircraft and might thus be frequently frozen. This eliminated mixtures containing water. The final recommendation was that two kits should be tried in practice and their respective values compared. Kit A of dark red vet. petrolatum and Kit B of dark red petrolatum with 10 per cent phenyl salicylate. The dark red petrolatum did not produce any irritation when applied daily to the skin of one investigator. [The effect upon sweating of the protective layer on the skin was not considered.]

TROPICAL ULCER.

BRECHER G. Ambulatory Treatment of Tropical Ulcers. *Trans Roy Soc Trop Med & Hyg* 1946, Apr v 39 No 5 449-54. (10 refs.)

In the southern peninsula of the Republic of Haiti West Indies facilities for the treatment of ulcers of the leg in hospital were inadequate so a routine form of ambulatory treatment was adopted, with good results. Yaws is almost universal in that part of Haiti and skin lesions of yaws were present in nearly half the patients treated for ulcer of the leg, but the author concluded that most of the ulcers could be regarded as tropical ulcers.

The routine local treatment used was the one introduced for chronic ulcers of the leg by BARROW of Bristol in 1799: heated adhesive strips [material not stated] 1 to 1 in wide were applied vertically or obliquely but not circularly and slightly overlapping each other so as to form an occlusive dressing over the ulcer and covering the surrounding skin for 3 ins above and below and 1 in. at the sides. This was covered by a bandage and the dressing was changed about once a week.

Systemic treatment was also given: neocarbazophenamine was injected intravenously and bismuth subsalicylate in oil intramuscularly once a week on the same day.

Of 205 cases so treated 147 (71 per cent) were known to have healed, the other 58 having been lost sight of. Of these 147 cases 51 (35 per cent.) healed in under 30 days 74 (50 per cent.) in 30-60 days 10 (7 per cent.) in 60-90 days, and 12 (8 per cent.) in 90-150 days. Of the 58 cases lost sight of, 48 had

improved and 12 were unimproved when last seen. Some complications are mentioned and there were two deaths which the author suspects were due to toxic nephritis caused by arsphenamine in patients with hookworm infestation. The author thinks that better results would have been obtained if the diet of the patients which was deficient in higher protein and calcium could have been improved.

MISCELLANEOUS DISEASES

POWER, S
572-3Funiculitis in British Troops in Ceylon. *Lancet* 1946 Apr 20

The author records an outbreak among the British troops of what for want of a better name may be called funiculitis. It occurred in Ceylon in 1943 after the onset of the south west monsoon. The disease was characterized by local induration of the spermatic cord due to thrombosis in the veins. Notes of two cases are given. No special treatment was required if seen at the onset the patients had a few days rest in bed, while if first seen later they were told to wear a suspensory bandage.

The author does not think that it was caused by filariasis although that would be suggested by its being endemic and seasonably epidemic in Ceylon. The locality was non-filarial none of the patients showed eosinophilia no filariae were found in the blood or hydrocele fluid, the pathology was not of the filarial type and filariasis is uncommon among Europeans [but see recent records of early filariasis among American troops abstracted in this *Bulletin*] [Endemic funiculitis is stated by MANSOY BAHR (Manson's Trop Dis. 1945 12th ed. London Cassell p 726) to be undoubtedly of filarial origin. It was described in Egypt by MADDEN (*Lancet* 1907 v 1 505) and COUTTS (*Ibid* 1909 v 1 227) and in Ceylon by CASTELLANI (*ibid* 1908 v 2, 15) who isolated a diplo-streptococcus which he thought was a secondary infection. CASTELLANI and CHALMERS (Manual of Trop Med. 1919 3rd ed. London Baillière Tindall and Cox p 1939) regarded it as a filarial condition with a superadded streptococcal infection. STEPHENS and YORKE (see The Practice of Medicine in the Tropics by BLAM and ARCHIBALD 1923 v 3 1920) considered it to be due to filariasis. STITT also (Diagnosis Prevention and Treatment of Tropical Diseases 1942 p 1317) regards it as filarial in origin. It was reported from Kenya by JEWELL (this *Bulletin* 1925 v 22 990) who was convinced that the disease was *sui generis*. CASTELLANI (*ibid* 1918 v 11 212) saw a case in Macedonia.]

GENERAL PROTOZOOLOGY

SENEKJIE H A. & LEWIS Ruth A. An Inquiry Into the Growth Factor or Factors of certain Blood and Tissue Flagellates. *Amer J Trop Med* 1945 July v 25 No 4 345-8.

The authors have studied the culture requirements of species of *Leishmania* and *Trypanosoma cruzi* with a view to the discovery of the growth promoting factor which exists in the blood. It was found that the factor is present in serum but is not directly associated with albumin, euglobulin, pseudoglobulin or combinations of these. It is not present in haemoglobin nor in washed erythrocytes. It is destroyed at a temperature of 100°C. but partially survives.

30 minutes exposure to 70°C. It was shown that para aminobenzoic acid, pyridoxine, nicotinic acid, thiamin and other vitamins tested, were all unable to take the place of the factor which is dialysable and is probably lost during the process of fractionating the serum proteins. C M Wexon

WEIDMAN D Human Toxoplasma. *Puerto Rico J Pub Health & Trop Med* 1944 Dec. v 20 No. 2, 125-81 4 pls. [Refs. in footnotes.] [Spanish version 162-63]

This is a useful general account of human toxoplasmosis based on published work of the author himself and others who have investigated the disease particularly in the United States during the past ten years. C M Wexon

DOW R. S. Toxoplasmic Encephalitis. Clinical Findings in 2 Patients from Pacific Northwest. *Northwest Med* 1945 Dec. v 44 392. [Summary taken from *J Amer Med Ass* 1946 Mar 23 v 130 No 12, 821-2.]

Dow presents the histories of two patients with toxoplasmic encephalitis. The first was a child aged 2 who exhibited all the clinical manifestations of toxoplasmic encephalitis including (1) healed or inactive choro-retinitis (2) reduced vision, (3) strabismus, nystagmus and microphthalmos (4) intracerebral calcification (5) one convulsive seizure (6) internal hydrocephalus from a block at the aqueduct of Sylvius (7) retarded speech development and (8) mental deficiency. The case was complicated by the presence of a postoperative *Staphylococcus aureus* meningitis and wound infection. The serologic tests for toxoplasma had not been done and attempts to infect laboratory animals with spinal fluid were unsuccessful. The second patient, a girl aged 5 exhibited many of the signs and symptoms of toxoplasmic encephalitis. Treatment with sulapyridine was tried and continued for ten days maintaining a blood level of 5 to 10 mg per cent. She seemed much improved for three weeks, but then seizures recurred. This observation and the results obtained in laboratory animals make it desirable to continue the use of sulfonamides whenever a diagnosis of toxoplasmic encephalitis is made and when there has not been extensive permanent cerebral damage. It is felt that the condition is more common than the reported cases would indicate and that a greater incidence will be found when knowledge of this disorder has become more generally available.

COWEN D & WOLF A Toxoplasmosis in the Monkey. Acute Fatal Infection experimentally produced in a Young *Macaca mulatta*. *J Infect. Dis* 1945 Sept-Oct v 77 No 2, 144-57 11 figs. on 2 pls. [25 refs.]

Earlier attempts to infect monkeys with toxoplasma have given negative results as regards the demonstration of parasites by microscopic examination of tissues. Some evidence was obtained, however that rhesus monkeys as determined by inoculation of blood into mice or by serological tests might acquire a transient infection. In the experiments described in this paper attempts were made to infect by intracerebral and other methods of inoculation nine rhesus monkeys of which two were immature animals 7 months of age, two were young adults and three were pregnant females and two were infants the offspring of the pregnant animals. In addition a young African green monkey (*Cercopithecus aethiops*) and an adult baboon (*Papio doguera*) were also injected. Of these animals one young rhesus monkey succumbed to the infection and showed toxoplasmic focal myositis and lesions in the rete testis. This is the first instance of active toxoplasmosis in a monkey with the production of lesions. Of the other 10 monkeys four gave a positive result

in serum neutralization tests for toxoplasmosis. Three monkeys including two of those giving a positive result in serum neutralization tests had myocardial lesions which were probably due to toxoplasmic infection though no parasites could be demonstrated in them. The attempt to produce congenital infection by the inoculation of the three pregnant monkeys was unsuccessful. From the experiments described in this paper which were carried out with a human strain maintained in mice and from the earlier work which is reviewed it is evident that primates are relatively unsusceptible to toxoplasmosis.

GENERAL ENTOMOLOGY

CAMERON T W M. *Insecticides and Repellents in Modern Medicine*
Reprinted from *McGill Med J* 1945 Oct. v 14 No 3 14 pp

This is a brief factual statement of information at present available on the insecticides and repellents now used in medicine and in it the author describes briefly the composition and effects of pyrethrum Lethane 384 Lethane 384 Special Thanite derris DDT DDD (the dichlorethane equivalent of DDT which has a similar action but is only about one-tenth as toxic to mammals) Gammexane the oils used as larvicides Paris green paradichlorbenzene orthodichlorbenzene and sodium arsenite. The repellents mentioned are oil of citronella with pyrethrum concentrate Indalone Rutgers 612 dimethyl and dibutyl phthallate a new repellent VMRI 201 developed in the United States and benzyl benzoate.

In so short a paper the information given is necessarily compressed and the outline is brief. Nevertheless this is a useful summary which a student of tropical medicine could read with advantage. The author points out that medical entomology saw its modern beginning with the work of Manson and that it is now the backbone of public health work in the tropics. Information has accumulated so rapidly during the war that there is need of summaries of this kind to make the subject clear to those who wish to keep abreast of research but who are not actively engaged in it.

Charles H Wilcocks

DAVID W A L. *Factors Influencing the Interaction of Insecticidal Mists and Flying Insects. Part I—The Design of a Spray Testing Chamber and some of its Properties.* *Bull Entom Res* 1946 Feb v 36 Pt. 4 373-93
4 figs [12 refs.]

The cabinet described was specifically designed for testing insecticides for use against mosquitoes but it can be used with other flying insects. It is a chamber in which temperature and humidity are controlled of 54.5 cu. ft. (1.543 litres) internal capacity into which the spray is atomized by an Aero-graph spray gun. The insects are exposed in wire frames covered with paper except for two wire mesh ends through which the spray can penetrate and knock-down counts can be made through special windows in the cabinet. These cages can be inserted or extracted without opening the cabinet door.

The author points out that the effects of variation in testing conditions are little understood, and testing of sprays has hitherto been done under arbitrary fixed conditions in order that tests may be repeated. Experiments were therefore planned to investigate various factors.

(i) The activity of the mosquitoes was very important because when the spray has evaporated down to floating particles (mist) the insecticide is mainly gathered by the insect as it flies through it. Very dilute pyrethrum preparations irritate the insects and stimulate flight, but this does not occur with DDT

sprays. The kill produced by the latter therefore depends to a large extent on the natural activity of the insects which varies in different cultures. To overcome this source of variability it is advisable to include a small, non-lethal concentration of pyrethrins so as to obtain uniform activity.

(ii) After the spray has been released, the more volatile fraction (kerosene) evaporates rapidly if the dose is below 15 cc. of liquid per 1 000 cu. ft. The chances of a drop of insecticide impinging on an insect are considerably reduced as the diameter falls below 5-10 microns. Therefore the concentration of non-volatile substance in the spray fluid is important and it can be shown that part of the effect of some synergizing materials (e.g. sesame oil, iso-butyl undecyleneamide) is due to the larger drops of spray left when they are present.

(iii) There is a positive correlation between temperature and susceptibility of the mosquito *Aedes aegypti* to pyrethrum as shown by results at 20°C. and 30°C.

(iv) The humidity during actual exposure however has little influence over normal ranges judging from results at 40 per cent. and 80 per cent. R.H.

(v) In this cabinet the time of introduction of the insects was investigated. Kill was highest when they were inserted before spraying and fell gradually to 10 minutes after spraying. The order of effectiveness of several formulae was not altered, however.

(vi) Some tests were made with insects flying freely in the cabinet, to compare with those in cages. The kills were higher in all cases when non-volatile constituents were added to the sprays but the relative results were similar.

J. R. BURTON

FAIRCHILD G. B. & BARREDA, E. A. DDT as a Larvicide against *Simulium*. *J. Econom. Entom.* 1945 Dec. v 38 No 6 694-9

The experiments aimed at eradication of *Simulium* spp. the vectors of *Onchocerca volvulus* in Guatemala and southern Mexico.

Experiments in Guatemala showed that addition of a 4 per cent. DDT emulsion concentrate to streams to give a dilution of one part DDT in ten million, killed *Simulium* larvae for a distance of ten kilometres along the stream.

Attempts to give a prolonged insecticidal action were made by compounding the DDT in blocks of plaster of paris in sawdust and in Esparto sponge gourds. Effective kills resulted, but lasted only one or two days.

Further tests showed that DDT powder made into a suspension in water with a wetting agent gave kills as satisfactory as those obtained with emulsions. It seems possible that this is due to aqueous solution of DDT at a rate of one part in 10 to 15 millions of water.

J. R. BURTON

EBELING W. DDT Penetration prevented by adding Aluminum Stearate to DDT Kerosene Solutions. *J. Econom. Entom.* 1945 Dec. v 38 No 6 689-91 1 fig

The addition of 1 per cent. aluminum stearate to kerosene greatly retards its penetration into foliage leaves. The effect when a DDT solution in kerosene (4 per cent.) is used, is to keep the solution on the surface of the leaves so that DDT crystals are left exposed instead of penetrating the plant. The effect is sufficiently great for trees which have been sprayed with DDT solution plus aluminum stearate to be picked out from controls (DDT solution only) by the visible white deposit.

J. R. BURTON

HOCKING H. S. The Use of "666" in the Control of *Ornithodoros moubata* Murray *East African Med J* 1946 Feb v 23 No 2 50-55

As the tick *O. moubata* normally lives beneath the surface of the soil it is difficult to eradicate it from infested buildings. 666 (benzene hexachloride crude material containing 12 per cent of the active gamma isomer) and DDT were tested in the laboratory and the field against this tick. Although the laboratory tests suggested that the 666 sprayed at a rate of 1,250 mgm. per square foot should give complete control in native huts it proved less effective though it substantially reduced the tick population. A second application of 666 three weeks later seemed to eliminate the ticks. DDT also reduced the number of ticks but was considerably less effective than the 666

KEARNS C. W. INGLE L. & METCALF R. L. A New Chlorinated Hydrocarbon Insecticide *J Econom Entom* 1945 Dec v 38 No 6 661-8

The compound has the empirical formula $C_{10}H_6Cl_6$ and is referred to as 1068. It is a colourless odourless viscous compound boiling at 175°C. It is readily soluble in most organic liquids and is completely miscible with odourless kerosene. The sample examined, which was at least 99 per cent pure showed no tendency to irritate skin or mucous membranes.

Insecticidal tests were made against a number of different insects in comparison with pure DDT and gamma benzene hexachloride. To the pea aphid (*Macrosiphum pisi*) the Colorado beetle (*Leptinotarsa decemlineata*) and the adult squash bug (*Anasa tristis*) 1068 was definitely more toxic than DDT.

As a residual film on wallboard 1068 was intermediate in speed of knockdown of *Anopheles quadrimaculatus* adults between DDT and benzene hexachloride the latter being most rapid. The order of efficiency as regards persistence was reversed DDT being most lasting.

Tests against larvae of *A. quadrimaculatus* indicated that the three substances were of the same order of toxicity.

Poot Grady tests with houseflies (*Musca domestica*) gave median lethal concentrations as follows: DDT 0.06 per cent and 1068 0.02 per cent.

Experiments in which solutions were delivered to the prothorax of individual roaches (*Periplaneta americana*) indicated a toxicity for 1068 three times as great as that of DDT.

Finally the various compounds were tested as stomach poisons for the grasshopper *Melanoplus differentialis*. The median lethal doses were —

gamma benzene hexachloride	5-10 micrograms per gram.
1068	12-25
DDT	over 50

GRANETT P. & HAYNES H. L. Insect Repellent Properties of 2-Ethylhexanedol-1,3. *J Econom Entom* 1945 Dec. v 38 No 6 671-5

The compound 2-ethylhexanedol 1,3 has been known during the war as Insect Repellent No 612 the test number assigned to it at Rutgers University. It is a slightly viscous colourless liquid having a mild odour resembling that of witch hazel. It is stable under extremes of storage conditions and, unlike certain other repellents its solvent action on certain materials is relatively weak. It will not attack cellulose acetate cellulose nitrate polystyrene vinylite resin UYNS Lucite or Plaskon. The vapour pressure at 20°C. is only 0.01 mm. and it boils at 244 C. and freezes below -40 C. Solubility in water is 4.2 per cent. at 20 C.

sprays. The kill produced by the latter therefore depends to a large extent on the natural activity of the insects which varies in different cultures. To overcome this source of variability it is advisable to include a small non-lethal concentration of pyrethrins so as to obtain uniform activity.

(ii) After the spray has been released, the more volatile fraction (kerosene) evaporates rapidly if the dose is below 15 cc. of liquid per 1 000 cu. ft. The chances of a drop of insecticide impinging on an insect are considerably reduced as the diameter falls below 5-10 microns. Therefore, the concentration of non-volatile substance in the spray fluid is important and it can be shown that part of the effect of some synergizing materials (e.g. sesame oil, iso-butyl undecylencamide) is due to the larger drops of spray left when they are present.

(iii) There is a positive correlation between temperature and susceptibility of the mosquito *Aedes aegypti* to pyrethrum as shown by results at 20°C. and 30°C.

(iv) The humidity during actual exposure however has little influence over normal ranges, judging from results at 40 per cent. and 80 per cent. R.H.

(v) In this cabinet the time of introduction of the insects was investigated. Kill was highest when they were inserted before spraying and fell gradually to 10 minutes after spraying. The order of effectiveness of several formulae was not altered, however.

(vi) Some tests were made with insects flying freely in the cabinet to compare with those in cages. The kills were higher in all cases when non-volatile constituents were added to the sprays but the relative results were similar.

J. R. BUSTINE

FAIRCHILD G. B. & BARRERA E. A. DDT as a Larvicide against *Simulium*
J. Econom. Entom. 1945 Dec. v 38 No. 6 604-9

The experiments aimed at eradication of *Simulium* spp. the vectors of *Onchocerca volvulus* in Guatemala and southern Mexico.

Experiments in Guatemala showed that addition of a 4 per cent. DDT emulsion concentrate to streams to give a dilution of one part DDT in ten million, killed *Simulium* larvae for a distance of ten kilometres along the stream.

Attempts to give a prolonged insecticidal action were made by compounding the DDT in blocks of plaster of paris in sawdust and in Esparto sponge gourd. Effective kills resulted but lasted only one or two days.

Further tests showed that DDT powder made into a suspension in water with a wetting agent gave kills as satisfactory as those obtained with emulsions. It seems possible that this is due to aqueous solution of DDT at a rate of one part in 10 to 15 millions of water.

EBELING W. DDT Penetration prevented by adding Aluminum Stearate to DDT Kerosene Solutions. *J. Econom. Entom.* 1945 Dec. v 38, No 6 689-91 1 fig

The addition of 1 per cent. aluminum stearate to kerosene greatly retards its penetration into foliage leaves. The effect when a DDT solution in kerosene (4 per cent.) is used, is to keep the solution on the surface of the leaves so that DDT crystals are left exposed instead of penetrating the plant. The effect is sufficiently great for trees which have been sprayed with DDT solution plus aluminum stearate to be picked out from controls (DDT solution only) by the visible white deposit.

J. R. BUSTINE

in 1943. It is certain however that these fleas must in the 1943 case have survived in some stage or other without a blood meal for three years which is longer than any laboratory record. The infestation apparently died out as there are no records of it in 1944 and 1945.

Fleas were not found on the pigs and they probably fed when the pigs were lying down.

RADFORD C D. Notes on *Trombicula deliensis* Walch, 1923 (Acarina: Trombidulidae), with Description of the Adult. *Parasitology* 1946 Jan. v 37 Nos. 1/2 42-5 9 figs.

An account is given of experiments made in an attempt to rear *Trombicula deliensis* a mite whose larva is believed to be an important vector of scrub typhus (tsutsugamushi disease). It proved impossible to complete the whole life-cycle in the laboratory, but all stages were obtained: nymphs from larvae attached to wild rats, bandicoots and shrews obtained by trapping and larvae from adults extracted from the soil. The nymphs died soon after moulting; too few larvae were obtained to continue the cycle. An account of the morphology of the adult which has not previously been described is given with some notes on its biology.

Kenneth Mellanby

RADFORD C D. Larval and Nymphal Mites (Acarina: Trombidulidae) from Ceylon and the Maldive Islands. *Parasitology* 1946 Jan. v 37 Nos. 1/2 46-54 29 figs.

Some details of the morphology of the larvae and nymphs (together with the adult of *Neoschöngastia indica*) of several species of Trombiculid mites of possible medical importance are given with notes on the technique used when attempting to breed them in the laboratory. One new genus of Trombiculidae *Womeraleya* and the genotype, *W. minuta* is described as this is parasitic on grasshoppers it is unlikely to be of medical importance.

Kenneth Mellanby

CARTER H F & D ABRERA V St E. Mites (Acarina)—a probable Factor in the Aetiology of Spasmodic Bronchitis and Asthma associated with High Eosinophilia. *Trans Roy Soc. Trop Med & Hyg* 1946 Apr. v 39 No 5 373-87 1 chart. [23 refs.]

Twenty-five Ceylonese patients all with a high eosinophilia (over 3 000 per cmm. as against a normal 500 per cmm. for individuals in the tropics) and all but one with bronchial asthma or other respiratory symptoms were investigated. Treatment was given with organic arsenicals and 24 out of 25 responded satisfactorily both as regards clinical symptoms and as to eosinophilia the latter being greatly reduced within three weeks.

Samples of sputum from these patients were collected with rigorous precautions to prevent contamination. Mites mostly tarsonemids or tyroglyphids were recovered from all cases. After treatment with arsenicals the number of mites was strikingly reduced. There is no doubt that these mites came from the lungs.

Most of the mites collected are normally found among food and stored products and it is suggested that some of these may be able at times to colonize the bronchi. Cases are described in which allied mites have been recovered from human tissues. These creatures are almost ubiquitous in tropical countries and can live under very diverse conditions so it is not impossible that they can invade living tissues. In some of the cases described it seems

In tests in which 1 cc. of material was applied to 100 square inches of skin the compound compared with dimethyl phthalate as follows —

Insect	Time to first bite	
	612	Dimethyl phthalate
<i>Aedes aegypti</i>	9 hr	7-8 hr
<i>Anopheles quadrimaculatus</i>	1 "	2 "
<i>Aedes sollicitans</i> }	6 "	4 "
<i>A. cantator</i>		
<i>Anopheles albimanus</i>	3-4	1½-2
<i>A. punctulatus foveoli</i>	6 "	1 "
<i>Stomoxys calcitrans</i>	1½-2 "	1 "
<i>Simulium</i> spp.	6 "	5½
<i>Phlebotomus</i> spp.	4 "	4 "
<i>Cimex phthalidis canis</i> }	2 "	4 "
<i>C. felis</i>		
<i>Extrambius</i> spp. }	on treated suits	
<i>Acariscus maroni</i>	30± days	30± days

It will be seen that "612" compares well with dimethyl phthalate, being more effective against all insects except *Anopheles quadrimaculatus* and the fleas. J R Burrins.

HATOFF A. Desensitization to Insect Bites. *J Amer Med Ass* 1946 Mar 30 v 130 No 13 850-54

"In a series of 129 susceptible infants and children 4 out of 5 were benefited by the use of flea antigen. This constitutes a demonstration of one method of developing host immunity to insect bites. The importance of this demonstration lies in the possibility of the use of such a method as an adjunct in the control of insect borne diseases."

FREEMAN R. B. The Pig as a Host of *Pulex irritans* L. (Siphonaptera, Pulicidae)
Reprinted from *Entomologist's Monthly Magazine* 1946 Jan. 30 v 82 19-21 [10 refs]

The human flea, *Pulex irritans* is found on many mammals but most of them especially rodents are probably not true hosts the flea being unable to maintain permanent colonies on them some however are true hosts the domestic pig being probably the most important while the dog is also often infested (see MAC ARTHUR this *Bulletin* 1946 v 43, 602). The author gives references to reports of the infestation of pigs in Great Britain, the United States of America, Argentina, Australia, and Morocco (this *Bulletin* 1923 v 23 916). LEWIS (Ga. Leckford Estate Andover 1938 v 1 104) reported an outbreak on a farm which had been famous for fleas for the past thirty years or more "they became a serious pest after the arrival of pigs on the farm."

A severe infestation of the pigs on a pig farm at Adderbury, Oxfordshire was investigated in 1938 all the farm buildings the two cottages and the yards were heavily infested and the surrounding fields contained considerable populations of the fleas "wherever the harmless looking mass of bits of straw and dry loam was disturbed it was seen to be a seething mass of jumping fleas" (quoted by the author from a report. Since the pigs were removed (apparently in 1940) severe outbreaks of flea infestation were noted twice in 1942 and once

in 1943 It is certain however that these fleas must in the 1943 case have survived in some stage or other without a blood meal for three years which is longer than any laboratory record. The infestation apparently died out as there are no records of it in 1944 and 1945
Fleas were not found on the pigs and they probably fed when the pigs were lying down

Samples of sputum from these patients were collected with rigorous precautions to prevent contamination. Mites mostly tarsonemids or tyroglyphids were recovered from all cases. After treatment with arsenicals the number of mites was strikingly reduced. There is no doubt that these mites came from the lungs.

Most of the mites collected are normally found among food and stored products and it is suggested that some of these may be able at times to colonize the bronchi. Cases are described in which allied mites have been recovered from human tissues. These creatures are almost ubiquitous in tropical countries and can live under very diverse conditions so it is not impossible that they can invade living tissues. In some of the cases described it seems

probable that the mites were really established as parasites in the lungs in others the mites were probably casual invaders.

The relation between the mites and the symptoms is discussed. A patient sensitized to the mites and their products would be likely to show more acute symptoms with only a few mites in the lungs than an unsensitized individual with a great parasite population. This may account for some apparent discrepancies in the results. The thesis that the mites may be the cause of the asthmatic symptoms and the eosinophilia seems to be well established by this work. LABORATORY PROCEDURES

BROWN R. L. Comparative Studies on Enterozoic Parasite Ova and Cysts Concentrating Procedures. *Amer J Trop Med* 1945 July v 25 No 4 375-8

The author has made a comparison of two techniques for the concentration of protozoal cysts and helminth eggs in faeces. These were the de Rivas acetic-acid-ether method (this *Bulletin* 1928 v 25 447) and the zinc sulphate method. In all cases the methods were applied to an emulsion of the faeces in physiological saline filtered through two layers of gauze. In the de Rivas method 5 cc. of the filtrate were shaken up with 30 cc. of 5 per cent acetic acid. The mixture was filtered through gauze, and an equal volume of ether was added. This was shaken until it jellied. It was then centrifuged. Two drops of the deposit were taken up and examined for cysts or ova. In the zinc sulphate method 5 cc. of the filtrate were diluted with 60 cc. of tap water and centrifuged. The fluid was poured off and the deposit taken up with tap water and again centrifuged. This process was repeated till the supernatant fluid remained clear. The sediment was then taken up in zinc sulphate solution of specific gravity 1.180 and again centrifuged. Two drops of the surface film were then pipetted off for examination. It was found that generally the zinc sulphate technique proved to be the more reliable though it occupied more time than the de Rivas method which in the case of some cysts and ova failed to concentrate at all. Furthermore the de Rivas method produced more distortion. For routine examinations the zinc sulphate method is to be preferred as it was much less selective concentrating more nearly uniformly all cysts and ova with a minimum of distortion.

REPORTS SURVEYS AND MISCELLANEOUS PAPERS

NAPIER, L. E. Teaching of Tropical Medicine. *Trans Roy Soc Trop Med & Hyg* 1946 Feb v 39 No. 4 273-82 Discussion pp. 283-300
[MANSON BARR, P. GORDON R. M. MACDONALD G. HODGE E. H. V.
DREW W. R. M. STANNIS H. S. TROWELL, H. C. CHRISTOPHERS
R. NAPIER, L. E. (in reply) SHORTT H. E.]

Dr Napier began his address by stating that Great Britain was rapidly losing any lead which it may have had in the field of tropical medicine and that the subject appeared to have been relegated to the place of a specialisation about which the general practitioner need know nothing and with which the ordinary undergraduate student should not be burdened. This unfortunate attitude was exemplified in the *Goodenough Report* where the existence of

parasites other than bacteria was apparently not recognized and in which there was no suggestion that the undergraduate student need be introduced to diseases which were not prevalent in his own country moreover under the heading of postgraduate teaching clinical tropical medicine was dismissed as a subject that could not possibly be taught in Britain The speaker emphasized the fallacy of segregating so-called tropical medicine of teaching parasitology to the student with bacteria as the only examples of parasites and while in his later years of teaching him virtually nothing of the pathology symptomatology and therapeutics of tropical diseases

Dr Napier next discussed how this unfortunate state of affairs might best be remedied In the undergraduate years it was of importance to avoid further overloading of the curriculum but much might be done by introducing the student during his pre-medical years to the pathogenic micro-organisms and worms and by substituting both in name and scope parasitology for bacteriology If this system were adopted it would leave the pathology symptomatology and therapeutics of important tropical diseases (many of which presented excellent opportunities for the teaching of the general principles of preventive medicine) to be taught in the systematic lectures on medicine in the wards and out patient departments when the occasion arose Such teaching would necessitate a generous supply of material for the practical classes in parasitology and for the teaching of clinical pathology and histology clinical material would have to be made available for the later years In the United States this difficulty was faced and overcome very early in the war by the co-operation of the Army Medical School at Washington which distributed suitable material to all the medical schools in the country Later some of the schools through their tropical connexions contributed to the common pool and the organization is at present receiving an abundance of material from the thousands of postgraduate students now serving in various tropical fields The importance of clinical material is obvious and a considerable amount of such material is now available in Britain although it is sometimes missed Dr Napier considered that during the next few years there would be an increasing number of cases of tropical diseases among the personnel of the fighting forces and among civilians whom the war has taken into the tropics Even in the absence of such cases however much could be done with the aid of a good set of lantern slides preferably in colour or better still with cinema films

As regards postgraduate teaching Dr Napier thought that it would be a tragedy with considerable political and financial as well as medical repercussions if we were to allow America or any other country to take the lead in the postgraduate teaching of tropical medicine and to attract to their country doctors and even patients from India and the Dominions the Colonies and foreign countries who would otherwise have come to London or Liverpool In London there was an abundance of clinical material which would show a marked increase during the succeeding years but at present no hospital where it could be collected The most crying need to-day was a tropical medical centre where all such persons returning from the tropics could go for diagnosis and treatment There was a popular misconception that in medical practice in any tropical country one would encounter a very large variety of the diseases usually labelled tropical Actually there were few if any places in the world where one could see a better selection of tropical diseases than in London The object of a post-graduate course in tropical medicine should be not to make the student an expert in all tropical diseases but to give him additional knowledge to enable him to take advantage of the opportunities to become an expert which would be provided in his subsequent practical experience in whatever tropical centres he might visit The speaker seriously questioned the value of instituting a higher diploma of specialist status in tropical medicine

legend beneath this reads " Enlargement of the scrotum (epididymis) is shown."

The section on dysentery is one of the best in the book. Bacillary amoebic, and balantidial dysentery are discussed in turn, each disease being illustrated by photographs of both morbid anatomical and histological material arranged to show the pathological processes underlying each disease. The complications of amoebic dysentery are set out in the form of a diagram. The section is completed by a group of photographs which illustrate some of the conditions which may be confused with bacillary or amoebic dysentery including tuberculosis of the gut, typhoid fever and ulcerative colitis. A small section on stool smears in dysentery is added.

There is a good account of the pathology of malaria, accompanied by illustrations which are admirable, with the exception of the coloured photomicrographs which are hard and lacking in detail.

One of the most interesting sections is that devoted to filariasis which is accompanied by 20 pages of photographs and diagrams, including a particularly clear one illustrating the differential diagnosis of the microfilariae.

The illustrations alone make this a book that should be found in every tropical medical library

TALICE, Rodolfo V. Profesor de la Facultad de Medicina de Montevideo (Uruguay), Jefe de Sección del Instituto de Higiene. *Enfermedades parasitarias del hombre y parásitos de interés médico. Etiología - Epidemiología - Patología - Clínica - Diagnóstico Tratamiento - Profilaxis.* [Parasitic Diseases of Man, and Parasites of Medical Interest.] Vol. I pp. xx+778, 189 figs., including 3 coloured pls. 1944. Editorial Científica del Sindicato Médico del Uruguay

This is the first volume of a treatise on parasitic diseases and was printed at the end of 1943 - we are not told how many volumes there are to be. The preface states that the book is intended for the practitioner and hygienist. Unlike so many other books dealing with parasites, in which too much attention is given to detailed descriptions of the parasites and too little to the diseases, this book attempts to do justice to both, so that it will be useful to the ordinary medical practitioner. It is intended primarily for S. America, as evidenced by the fact that 5 pages only are given to African trypanosomiasis and 170 to that of S. America.

Volume I is devoted to a consideration of the intestinal protozoa, leishmaniasis, trypanosomiasis and spirochaetosis, including rat-bite fever, syphilis and yaws, etc. Under these headings dealt with from the South American point of view a vast amount of information is given, somewhat uncritically most of it being quotations from the literature.

There are three coloured plates, one fairly good showing intestinal protozoal cysts in iodine, a second giving the appearance of *Trypanosoma cruzi* in Giemsa-stained thick films, and a third and somewhat striking one of the appearance of an opened-up gumoeing illustrating the pain and haemorrhage of Weil's disease. There are about 190 figures in black and white. These are poor and in some cases so bad that they fail to illustrate what is intended.

CONTROL OF SCHISTOSOMIASIS

By J. J. C. BUCKLEY D.Sc.

Lecturer in the Department of Parasitology London School of Hygiene and Tropical Medicine (University of London)

Any approach to the problem of schistosomiasis control whether it be an investigation or some more direct attempt to reduce the incidence of the disease will naturally be made from the standpoint of one or both of the main principles—prevention and treatment. Preventive methods in schistosomiasis are concerned with some phase in the rather complicated but well known life-cycle of the parasite and their efficacy and expediency are determined by factors which may vary with local exigencies of topography and custom. Treatment in schistosomiasis which in this instance obviously implies mass treatment involves the use of drugs—experience has shown that certain derivatives of antimony are the only effective if not highly efficient curative agents.

Prevention

In recent years a considerable amount of research has been carried out and field trials have been attempted in several regions to control schistosomiasis by the preventive method with varying degrees of success. A general account of these is presented here under three headings: 1. Protection of snail-bearing waters from fouling and infection. 2. Destruction or reduction of snail populations. 3. Avoidance of cercarial infection.

1. *Protection of snail habitats from infection*.—The means for achieving this very desirable objective and thus breaking the bilharzia life-cycle at its outset may not always be to hand nor easily applied, but the advantages of this form of control are manifold whether it be achieved by education and propaganda or by some more directly practical measures. Considerable success in this direction appears to have attended the efforts of the Sudan Medical Service [Report of the Sudan Medical Service for the year 1936 (this *Bulletin* 1938 v 35 266)]. Sanitary measures were employed, which comprised the placing of all villages at least 300 metres from snail infested canals which in addition were fenced and the provision of good wells and latrines near the villages. These measures, combined with treatment have resulted in substantial reductions in the schistosomiasis incidence in parts of the Northern Province in the Wadi Halfa District and in the Blue Nile Province.

2. *Destruction of snails*.—The most obvious and usually the most practicable method of breaking the bilharzia life-cycle is to kill or get rid of the snail intermediaries and since the researches and recommendations of LEIPER in Egypt (this *Bulletin* 1915 v 6 437) opened up this field of attack in 1915

The section is completed by a group of photographs which illustrate some of the conditions which may be confused with bacillary or amoebic dysentery including tuberculosis of the gut, typhoid fever and ulcerative colitis. A small section on stool smears in dysentery is added.

There is a good account of the pathology of malaria, accompanied by illustrations which are admirable with the exception of the coloured photomicrographs which are hazy and lacking in detail.

One of the most interesting sections is that devoted to filariasis which is accompanied by 20 pages of photographs and diagrams including a particularly clear one illustrating the differential diagnosis of the microfilariae.

The illustrations alone make this a book that should be found in every tropical medical library

B G Macgregor

TALICE, Rodolfo V [Profesor de la Facultad de Medicina de Montevideo (Uruguay) Jefe de Sección del Instituto de Higiene] *Enfermedades parasitarias del hombre y parásitos de interés médico. Etiología. Epidemiología. Patología Clínica. Diagnóstico. Tratamiento-Profilaxis.* [Parasitic Diseases of Man and Parasites of Medical Interest.] Vol 1 pp xx+778, 189 figs. including 3 coloured pls. 1944 Editorial Científica del Sindicato Médico del Uruguay

This is the first volume of a treatise on parasitic diseases and was printed at the end of 1943. We are not told how many volumes there are to be. The preface states that the book is intended for the practitioner and hygienist. Unlike so many other books dealing with parasites in which too much attention is given to detailed descriptions of the parasites and too little to the diseases, this book attempts to do justice to both, so that it will be useful to the ordinary medical practitioner. It is intended primarily for S America as evidenced by the fact that 5 pages only are given to African trypanosomiasis, and 170 to that of S America.

Volume 1 is devoted to a consideration of the intestinal protozoa, leishmaniasis, trypanosomiasis and spirochaetosis, including rat bite fever, syphilis and yaws, etc. Under these headings dealt with from the South American point of view a vast amount of information is given, somewhat uncritically most of it being quotations from the literature.

There are three coloured plates, one fairly good showing intestinal protozoal cysts in iodine, a second giving the appearance of *Trypanosoma cruzi* in Giemsa stained thick films, and a third and somewhat striking one of the appearance of an opened up guinea pig illustrating the jaundice and haemorrhage of Weil's disease. There are about 180 figures in black and white. These are poor and in some cases so bad that they fail to illustrate what is intended.

CONTROL OF SCHISTOSOMIASIS

By J J C BUCKLEY D.Sc.

Lecturer in the Department of Parasitology London School of Hygiene and Tropical Medicine (University of London)

Any approach to the problem of schistosomiasis control, whether it be an investigation or some more direct attempt to reduce the incidence of the disease will naturally be made from the standpoint of one or both of the main principles—prevention and treatment. Preventive methods in schistosomiasis are concerned with some phase in the rather complicated but well known life-cycle of the parasite and their efficacy and expediency are determined by factors which may vary with local exigencies of topography and custom. Treatment in schistosomiasis which in this instance obviously implies mass treatment involves the use of drugs experience has shown that certain derivatives of antimony are the only effective if not highly efficient curative agents

Prevention

In recent years a considerable amount of research has been carried out, and field trials have been attempted in several regions to control schistosomiasis by the preventive method with varying degrees of success. A general account of these is presented here under three headings 1 Protection of snail-bearing waters from fouling and infection. 2 Destruction or reduction of snail populations. 3 Avoidance of cercarial infection

1 *Protection of snail habitats from infection*—The means for achieving this very desirable objective and thus breaking the bilharzia life-cycle at its outset may not always be to hand, nor easily applied but the advantages of this form of control are manifold whether it be achieved by education and propaganda or by some more directly practical measures. Considerable success in this direction appears to have attended the efforts of the Sudan Medical Service [Report of the Sudan Medical Service for the year 1936 (this *Bulletin* 1938 v 35 266)] Sanitary measures were employed which comprised the placing of all villages at least 300 metres from snail-infested canals which in addition were fenced and the provision of good wells and latrines near the villages. These measures, combined with treatment have resulted in substantial reductions in the schistosomiasis incidence in parts of the Northern Province, in the Wadi Halfa District and in the Blue Nile Province.

2 *Destruction of snails*.—The most obvious and usually the most practicable method of breaking the bilharzia life-cycle is to kill or get rid of the snail intermediaries and since the researches and recommendations of LEIPER in Egypt [this *Bulletin* 1915 v 6 437] opened up this field of attack in 1915

most of the anti-bilharzia campaigns in subsequent years have been based on this principle.

The methods of snail control in operation or suggested in endemic areas are mainly as follows: the introduction of chemical or organic poisons into snail habitats; the removal of snails by manual labour; the removal of vegetation and other necessary elements in their environment; biological control by the introduction or encouragement of natural enemies or unsuitable types of vegetation; the reconstruction of natural watercourses (e.g. by canalization, cementing or covering); flushing, draining and drying of watercourses and the removal of unnecessary bodies of water.

The most widely-used chemicals for snail destruction are copper sulphate, copper carbonate, slaked lime and ammonium sulphate. KHALIL and AZIM [this *Bulletin* 1938 v 35 667] used copper sulphate in a concentration of 5 parts per million for 5 days in the streams and channels of the Dakhla Oasis, Egypt, and found it effective. BAUGÉ [this *Bulletin* 1942, v 39 768] also obtained good results in Southern Tunisia with copper sulphate in a focus of *S. haematobium*. This salt has the disadvantage of rendering water unfit for human consumption for a while, but in Southern Rhodesia MOXLEY [this *Bulletin* 1942, v 39 11] found that malachite (mineralized basic copper carbonate) is just as effective and less toxic; on the other hand it is more expensive and less soluble. The system of control employed in Fayoum Province [BARLOW and AZIM, this *Bulletin* 1945 v 42, 1017] combines copper sulphate treatment of the larger canals with manual clearance of snails and vegetation from the lesser water-courses. The concentration of copper sulphate varies from 15 to 50 parts per million according to the amount of silt and vegetation present. At Oran in Algeria, a new focus of urinary schistosomiasis appeared after the initiation of an irrigation system, which created an immense habitat favourable for snails (ALCAY, MARILL and MUSSO, this *Bulletin* 1943 v 40 467). It was suggested that these canals be controlled by emptying and cleaning, but it is pointed out that it would be a measure of only temporary value since the canals become restocked with snails from some natural source which should be found and controlled. [The dangers of "man-made" snail habitats of another kind have been indicated by MOXLEY (this *Bulletin* 1945 v 42 516) in Southern Rhodesia, where small artificial pools polluted with human dejecta and litter become more heavily stocked with snails than are natural waters.]

In Venezuela, LUTERMOSEER [this *Bulletin* 1943 v 40 849] records the successful control of *Planorbis* (*Australorbis*) *glabratus*, vector of *S. mansoni*, by the application of recently slaked lime to the waterways. He found that a 0.1 per cent. solution kills snails and eggs in a day or less. In field practice several treatments of canals, cement tanks and $\frac{1}{2}$ kilometre of a river kept the water free of snails for 6 months, but one treatment every 3 months was usually sufficient. Lime has the advantage also of being non-toxic to domestic animals and cultivated land, and possesses a useful anti-bacterial and cercarial action. JANKEN [this *Bulletin* 1945 v 42, 1018] also tested the effect of slaked lime in Catende, Pernambuco, against *Planorbis* (*A.*) *centricentratus* and obtained 100 per cent. snail mortality with a strength of 4-5 parts per thousand after 24 hours. The use of lime is deprecated by MOXLEY [this *Bulletin*, 1945 v 42, 516] in Southern Rhodesia, since by increasing the lime availability it may encourage snail development in lime-deficient areas. He considers that quicklime is ineffective against bilharzia snails as a result of his experience in treating a small stream containing *Physopsis* and *Biomphalaria*.

Doubts about the efficacy of drying as a means of snail control have been raised by several workers. BRUNET [this *Bulletin* 1942, v 39 866] states that *Planorbis* (*A.*) *glabratus* has considerable resistance to drying, and that after

nate drying and filling of canals every 15 days is not effective. In laboratory experiments this species survived 50 days of drying more severe than would occur in nature. According to BARLOW and AZIM [this *Bulletin* 1945 v 42 1017] *Bulinus truncatus* is not killed by emptying and drying canals for 40 days and in laboratory tests this species revived after 12 months and *Planorbis boissys* after 10 months desiccation in mud.

The amphibious intermediary of *S. japonicum* *Blanfordia (Oncomelania) nosophora* requires a somewhat different method of attack. MIRAJIMA [this *Bulletin* 1939 v 36 623] describes the control of this species which lives partly in the water of ditches and partly on their muddy and weedy margins by applications of quicklime to the water in a strength of 1 per cent. for 10 hours while snails outside the water are killed by a steam jet. Control measures against *S. japonicum* must take into account the fact that it is harboured by other definitive hosts as well as man. WU [this *Bulletin* 1941 v 38 43] found the following animals naturally infected in China: sheep, goats, house-rats, dogs, cats, oxen, buffaloes and horses.

Biological control of snails by means of natural enemies such as ducks, hedgehogs and fish is undoubtedly valuable but is practicable in only a limited range of circumstances. A case for bilharzia control by fish in South Africa and Rhodesia has been stated by CAWSTON [this *Bulletin* 1937 v 34 797]. Biological control by means of aquatic plants such as *Pistia stratiotes* has been suggested by MOZLEY [this *Bulletin* 1940 v 37 483] who noted that in Zanzibar and Tanganyika Territory snails are scanty in water whose surface is completely covered by aquatic or semi-aquatic plants. Biological control by planting *Balanites* trees along snail-infested watercourses has also been suggested. ARCHIBALD [this *Bulletin* 1934 v 31 114] found that the fruit of this tree (*B. aegyptiaca* in Tropical Africa, Arabia, Egypt and Palestine) if treated in a certain way produces a poison which is highly fatal to snails and WAGER [this *Bulletin* 1936 v 33 557] noted that the fruit of the South African species *B. maughamsi* has similar properties. It is also very toxic to other forms of aquatic life such as tadpoles, frogs, fish etc. and its value as a snail-killer may therefore be offset by the danger of upsetting the balance of life in natural waters.

3 *Avoidance of cercarial infection*—Individual prophylaxis is theoretically simple and consists merely in avoiding skin-contact with or the drinking of infected water but this doctrine implies that persons liable to exposure are aware of the life-cycle of the parasite and may be nullified by the requirements of agricultural practice in some countries. BRACKETT [this *Bulletin* 1940 v 37 149] showed experimentally that the cercariae responsible for schistosome dermatitis penetrate skin mainly when water is evaporating from it so that vigorous wiping after bathing is a useful prophylaxis. The well known fact that schistosome cercariae do not live longer than 48 hours in water can also be used in prophylaxis in certain circumstances.

Researches on cercaricidal substances have mostly centred about the effects of chlorine. WITENBERG and YOFFE [this *Bulletin* 1938 v 35 600] found chloramine more efficient than gaseous chlorine or sodium hypochlorite the concentrations necessary being 0.22 part per million residual after 10 minutes application for chloramine, 0.42 for sodium hypochlorite and 0.6 for gaseous chlorine. MAGATH's experiments [this *Bulletin* 1943 v 40 156] indicated that chlorination of 0.2 part per million [residual of 0.1 p.p.m. after 30 minutes] kills cercariae of *S. mansoni* in 30 minutes. OLIVER GONZÁLEZ BIAGGI and RIVERA LEÓN [this *Bulletin* 1946 v 43 347] suggest from experimental results that a minimum exposure of 20 minutes to the effects of a chlorine solution yielding a minimum chlorine residual of 0.5 part per million may be sufficient to render cercariae non-infective. KRAKOWER [this *Bulletin* 1941 v 38 376]

subjected the cercariae of *S. mansoni* to a variety of physical conditions and found that their normal span of life in rain water is 24-48 hours rarely 72 hours. They survive up to 14 days at 5°-6°C. but remain motionless, while freezing is rapidly fatal. Above 34°C. the mortality increases and at 43°C. all die in 30 minutes. Strong electric light induces activity and shortens the span of life while ultraviolet light and direct sunlight are both fatal, but the heat of the sun may also be an adverse factor in this instance. Extremes of pH outside the 4-6-10 range are fatal and cercariae are rapidly killed in a 1.5 per cent. solution of sodium chloride.

Treatment.

The efficacy of prevention in an anti-bilharzial scheme must necessarily be greatly enhanced by concurrent treatment of the infected population, which stems the source of snail-infection at its origin but the prolonged and tedious procedure of present-day methods of chemotherapy in schistosomiasis is very unsuitable for mass treatment. In this connexion the researches of ALVES [this *Bulletin* 1945 v 42, 815] and ALVES and BLAIR [*ibid* 1946 v 43 344] on an intensive treatment with sodium antimonyl tartrate in Southern Rhodesia are most opportune and have an important bearing on the present problem. These authors devised a course of treatment of only 2 days duration which consists of six intravenous injections each of 1-2 grains of S.A.T. In a trial of 100 cases all positive by intradermal tests and by examination of stools or of urine none was passing eggs two months after treatment and a high proportion were negative by the skin test. Toxic complications were unimportant and transient. This treatment was subsequently modified to a course of one day only with smaller dosage [ALVES below p. 752] which was tried out on a group of 131 cases all positive by the skin test. Four weeks later none of these was passing eggs. While the follow up of these cases is as yet incomplete and the possibility of relapses is admitted the importance of the treatment is manifest, for it provides a means of rapidly disinfecting an infected population for a time at least, which would offer a breathing-space in the struggle to break the life-cycle in bilharzias since our snail-killing will be at a peak at, and immediately after the time when the population's infectivity is at its lowest and those adult snails which escape killing will also escape infection.

If the promise held out by these researches is fulfilled a great advance in the control of schistosomiasis will have been achieved.

SUMMARY OF RECENT ABSTRACTS *

VII. HELMINTHIASIS

General

VASILKOVA (p. 509) has examined the water of the river Moskva, in Russia, for helminth eggs. The main source of contamination was the effluent from a sewage works, and in water from this source 4,500 eggs per cubic metre were found, including those of *Ascaris Trichuris Taenia* and *Diphylllobothrium*. *Enterobius* and *Dicrocoelium* eggs were found in the river water. Some of the eggs were viable. A degree of natural cleansing of the river water takes place by settlement, but better methods of purifying sewage water are needed. In the meantime people may infect themselves from the river.

The information from which this series of summaries has been compiled is given in the abstracts which have appeared in the *Tropical Diseases Bulletin* 1945 v 42. References to the abstracts are given under the names of the authors quoted and the pages on which the abstracts are printed.

NIÑO (p 473) discusses appendicitis in which there is associated helminth infestation of the appendix. He found worms in 3.17 per cent of 1763 appendices examined. In by far the majority of cases the worm was *Enterobius vermicularis*.

OLIVER-GONZÁLEZ and TORREGROSA (p 45) have isolated a substance from certain helminths infesting man which is related to human isoagglutinins.

A Symposium on Anthelmintics (p 570) has been published in the United States.

ROGERS (p 299) has made a very thorough study of the anthelmintic activity of hexylresorcinol and tetrachlorethylene using the perfused small intestine of rats infested with *Nippostrongylus muris* for the purpose. Details of the many observations should be sought in the original abstract but the main conclusions are that the efficiency of hexylresorcinol is reduced by sodium taurocholate, and that the drug is adsorbed on to mucin which prevents its penetration into the parasites. The latter appear to stimulate the formation of mucus in the intestine and are to a very considerable extent protected by the mucus on the intestinal wall. Tetrachlorethylene on the other hand stimulates *N. muris* to leave mucus and to enter fluids in the intestinal lumen. It is not inhibited by bile salts and acts rapidly in the rat. Sodium laurate and sodium oleate show intrinsic anthelmintic properties: the former activates hexylresorcinol more than the latter.

PARANJAPÉ *et al* (p 571) have investigated the anthelmintic action of certain synthetic lactones and compounds allied to santonin. In their work they used earthworms, commenting on this fact LAPAGE gives reasons why *Ascaris* of the pig would provide a more satisfactory test.

Trematodes

General—SILVEIRA (p 46) in a discussion of pulmonary schistosomiasis notes that this condition is much less common in *S. mansoni* than in *S. haematobium* infections and explains this by reference to routes available in the venous system to each of these trematodes. Nevertheless pulmonary schistosomiasis due to *S. mansoni* is not uncommon. There are two stages: acute (during the stage of migration through the lung) which is the toxæmic form and may even be fatal; and chronic (due to adult worms or eggs in the lung). Clinically there are two forms with respiratory symptoms or with symptoms of embarrassment of the pulmonary circulation. The only certain diagnosis is the finding of eggs in the sputum, since radiological signs are not characteristic.

Schistosoma haematobium—Vesical schistosomiasis is prevalent in Angola. In one area SARMENTO (p 1015) found infection in 60 per cent of children and in 21.5 per cent of adults. ANDREASEN and SURI (p 742) report what appears to be the first recorded case of infection with *Schistosoma haematobium* contracted in India. [The importance of such a finding is sufficiently obvious: the disease was well established in this patient and the authors think that he probably acquired it in his home village.]

GORSSE and ACCART (p 395) review the results of treatment of over 200 cases of urinary schistosomiasis. They argue that the best estimate of treatment can be obtained by cystoscopy and they describe the appearances to be seen by this means at different stages of the infection. The results of treatment with tartar emetic, Fouadin and anthiomaline were not satisfactory: the last of these being the best. Nevertheless antimony though not specific, is the most useful drug but in some cases seems to be insufficient by itself. An intensive course of treatment of schistosomiasis with a preparation of sodium antimonyl tartrate is described by ALVES (p 815). The whole course

consists of a total dosage of 12 mgm. of the drug per kgm. body weight and the injections are given intravenously at intervals of 2 to 2½ hours over a period of 30 hours with a break of some 16 hours after the first day of treatment. The injections are given very slowly and the drug is well diluted in glucose-saline. Results appear to be promising.

STEPHENSON (p. 572) has treated nine patients infested with *Schistosoma haematobium* with stilbamidine, but concludes that the action of this drug is too uncertain to justify its routine use in urinary schistosomiasis.

S. mansoni.—In Pernambuco infection with *S. mansoni* is common, and MAGALHÃES (A.) *et al.* (p. 1016) show that the infection rate is highest in late childhood and young adult life. Males are rather more commonly affected than females.

DI GIACOMO and MAYER (p. 47) make the point that infection with *S. mansoni* may be very insidious, and that stool examination should be made on all persons from endemic areas whether or not there are suggestive symptoms.

WRIGHT and ROBERTS (p. 215) describe the early symptoms of infection with *S. mansoni* in a boy who shortly after contracting this infection showed creeping eruption which the authors think was due to larvae of *S. mansoni*. At the time when the creeping eruption was noticed, the boy was suffering from urticaria. He subsequently developed intense eosinophilia.

BERCOVITZ *et al.* (pp. 47-572) found small ulcers on proctoscopic examination of recruits in Porto Rico who had eggs of *S. mansoni* in their faeces. The blood picture showed little departure from the normal.

ALMY and HARPER (p. 646) report a case of chronic infection with *S. mansoni* in which Banti's syndrome developed. ALMY and HARPER (p. 815) also describe a case of long-standing infection with *S. mansoni* in which there were associated signs of Banti's disease.

SAXABRIA (p. 396) describes two patients, with bilharzial myocarditis in whom the Stokes-Adams syndrome was present. MEIRA and RAMOS (p. 572) discuss two forms of myocarditis which may occur in infestation with *S. mansoni* but in part of a thesis on *S. mansoni* infection MAGALHÃES (B. F.) and DIAS (p. 1016) make a note of the fact that in 22 autopsies they failed to find myocardial lesions, and that ova have not been found in the heart muscle. They think, therefore that it is highly improbable that there is a cardiac form of the disease.

CRAM *et al.* (p. 646) have shown that the snail *Tropisorbis hartmanni*, indigenous to the United States is susceptible to infection with *S. mansoni*.

Bulinus truncatus is a carrier of bilharzia in the Fayoum Province of Egypt. BARLOW and ABDEL AZIM (p. 1017) describe control measures used in Egypt against this and other snails. There are two main methods—mechanical clearance of small streams by means of standardized hand nets, and the use of copper sulphate in larger canals. For the latter concentrations of 15–50 parts per million are required in field work. Snails live a long time, but probably not more than 2 years—desiccation for 40 days cannot be relied upon to kill them since they have been known to revive after 12 months desiccation in mud. JAMSON (p. 1018) has found that slaked lime in a strength of 4–5 parts per 1,000 and copper sulphate in a strength of 2 parts per 1,000 are effective in killing *Australorbis centricornis* the host of *S. mansoni* in Pernambuco.

KRAKOWER *et al.* (p. 133) have found that eggs of *S. mansoni* in guineapigs kept on a diet deficient in vitamin C, tend to show disintegration of the shells. Deficiency of vitamin C did not, however interfere with the development of *Schistosoma*.

S. japonicum.—An account of the symptoms of the early stage of schistosomiasis japonica is given by THOMAS and GAGE (p 1018). There is usually fever with headache cough possibly abdominal symptoms and in some cases urticaria. The liver is usually enlarged and tender the spleen less commonly so. Eosinophilia is characteristic. Eggs are found in the faeces some 6–10 weeks after infection they may be present in patients who have had no more than trivial symptoms.

In the *Bulletin of the U.S. Army Medical Department* (p. 1019) the treatment of schistosomiasis japonica is discussed and Fouadin and tartar emetic are the drugs advocated. Each may be toxic, and each should be injected slowly. Fouadin should be tried first. For details of administration the original abstract should be consulted.

Other trematodes.—STEPHENSON (p 474) has found that *Fasciola hepatica* will live for 60 hours at 38°C in a solution containing NaCl KCl CaCl₂, borax and glucose of pH 8.6. This is adequate for the preliminary testing of anthelmintics in such tests carbon tetrachloride was found to be innocuous though it is probably the best anthelmintic in man.

WITENBERG (p 396) has found a fluke, *Clinostoma complanatum* in man it caused laryngo-pharyngitis. This infection is apparently due to the eating of fish infested with metacercariae of the fluke.

CORT (p 905) discusses the germ-cell cycle in the digenetic trematodes. The subject is complex, and cannot briefly be dealt with the original should be consulted by those interested.

Cestodes

In a series of four papers TÖTTERMAN (p 215) discusses the anaemias which occur in a small proportion of people infested with *Diphyllobothrium latum*. He estimates that about 14 per cent of people in Finland are infested by this worm. The well-known anaemia is indistinguishable from pernicious anaemia, but there is another and more common form, a light hyperchromic anaemia, which he regards not as a stage in the development of the former but as a separate condition. In this anaemia liver preparations have no effect but improvement follows administration of a vermifuge, whereas in the pernicious form liver is useful. The light anaemia is probably due to absorption of toxins from the worm which alone will not cause the 'pernicious' form.

Treatment of the pernicious anaemia with yeast, which is rich in Castle's extrinsic factor has given good results but the author has not been successful with certain extracts of hog stomach. He argues that the pernicious anaemia of *D. latum* infestation occurs in patients who have become sensitized to the tapeworm and quotes his own experiments which showed that in sensitized persons but not in normal controls administration by injection of an alcoholic extract of the worm tended to produce a 'pernicious' form of anaemia.

GIBSON (p 396) reports the discovery of species of *Diphyllobothrium* in trout in England, and UKSWORTH (p 397) discusses the recent findings of tapeworms of this genus in fish and in birds in England and Ireland. He concludes that the evidence is against their being *D. latum* but in comment LAPAGE suggests that the relationship between the tapeworms of birds and *D. latum* needs further study. BAYLIS (p 906) also discusses the species of *Diphyllobothrium* found in trout and in birds in the British Isles and differentiates them from *D. latum*.

DIXON and HARGREAVES (p 907) report on 284 cases of cerebral cysticercosis. In 89 per cent of proved cases radiographic examination of the skull failed to show the parasites and the point is made that only in a minority of cases do the degenerative changes in these intracerebral cysts go on to calcification.

The authors discuss prognosis, and in comment MACARTHUR points out that relapse may follow a symptom-free period lasting as long as 20 years. The original paper should be read by those interested in this condition.

ARANA and ASEJO (p. 908) have made ventriculographic examinations in 20 cases of cerebral cysticercosis in which the parasites were sub-tentorial. All cases were verified. The radiological findings should be studied in the original.

SELMAN (p. 816) describes a case of eosinophilia of the blood and of the cerebrospinal fluid, in a patient who showed signs of meningeal irritation. The author thinks that this was probably a case of cerebral cysticercosis. A similar case is referred to by APPLERBAUM and WEXBERG (p. 816).

MAZZOTTI (p. 647) gives information on cysticercosis in Mexico and again refers to the high proportion of positive results obtained in infestations with *T. saginata* by examination of the perianal region by means of swabs. This suggests the possibility of auto-infection, and similar findings have been made in the case of *T. solium* but not, apparently, to anything like the same extent, probably because the proglottides of *T. solium* do not emerge spontaneously as do those of *T. saginata* but only with the faeces.

The same author (pp. 134-398) made 108 examinations of the perianal region, by means of the Graham adhesive cellulose tape method, in 10 persons infested with *Taenia saginata*. Of these examinations, 85 per cent. were positive, whereas with direct smear examination of faeces, the proportion was very much smaller. Eggs were also found on other areas of skin between the neck and the knees, and on the underclothes. On examining the proglottides of the worm he found that the branches of the uterus communicate with the exterior when the proglottid is detached, and that disintegration is therefore not essential for expulsion of eggs.

NISO (p. 909) thinks that Acramil, an acridine derivative of the mepacrine type, is the ideal anthelmintic for the treatment of infestation with *Taenia saginata*. Of 41 patients 34 were cured by a single treatment, and four others after more than one. Details of administration are given in the original abstract.

RIVAS *et al.* (p. 910) give details of the statistics of hydatid disease in patients treated at the Institute of Clinical Surgery, Buenos Aires. The amount of information given cannot satisfactorily be summarized, and the original abstract should therefore be consulted.

BARRITT and THOMAS (p. 474) have written a long paper on pulmonary hydatid disease. It is not possible to do justice to all the points raised, for which the original should be consulted but certain statements may be noted. The presenting symptom is usually haemoptysis, but the first signs and symptoms may be due to anaphylaxis. Sudden expectoration of a large amount of clear salt tasting fluid is diagnostic of the rupture of a simple cyst. Pulmonary hydatid cysts should never be aspirated. The parasite should be removed at the earliest possible moment the safest way to enucleate a simple cyst is to treat it as a lung abscess, but in a selected group of cases the treatment of choice is lobectomy.

CASTRO (p. 573) discusses hydatid disease of bone. Prognosis in these cases is grave and for affected bones of the limbs, amputation is usually necessary. Hydatid disease of the spine is always fatal. HOWORTH (p. 817) also refers to the fact that treatment of hydatid cysts of bone is still unsatisfactory.

Treatment of infestations with *Hymenolepis* in children by means of male fern given in cycles was found unsatisfactory by PODYAPOLSKAYA and ISACHENKO (p. 573) who therefore experimented with other drugs given in association with male fern. Of these the most effective was methylene blue,

but yatren was also useful. For details of administration the original abstract should be consulted. GORIACHEVA (p 575) has tried this method and regards it as the best yet available. He prefers it to the use of pumpkin seeds or of full doses of male fern both of which he tested.

In a study of the vitamin requirements of cestodes ADDIS and CHANDLER (p 302) found that *Hymenolepis diminuta* was markedly affected by lack of vitamins in the diet of the host, if the latter was a female rat but not if it was a male (Chandler). They therefore worked with female rats and discovered that the vitamin concerned was riboflavin. If this was withheld, the number and size of the infesting cestodes were smaller than in rats on full diet and the longer the vitamin had been withheld the more marked the effect. On the other hand when vitamins A, D, E and B were lacking the worms grew rather longer than shorter. The cestodes obtain their protein by absorption direct from the mucosa of the host not from the contents of the intestine [and presumably they obtain riboflavin in the same way].

KOURI (p 477) reports that up to 1944 more than 70 cases of infestation with *Inermicapsifer cubensis* had been reported usually in young children. Man is probably not the normal host and appears to be an unfavourable host but examination of a large number of mammals, acari, insects and crustacea has failed to reveal the parasite.

Charles W. S. Coombs

MALARIA.

PROKOPENKO L. I. [Analysis of the Causes of the Severe Epidemic of Malaria in 1942 in Urgut District of the Samarkand Province and Measures for the Prevention of Increase of Malaria Morbidity in 1943.] *Med. Parazit. & Parazit. Dis.* Moscow 1945 v 14 No 3 15-33 5 figs. [In Russian.]

The author records the results of observations made by an expedition organized by the Moscow and Uzbek Malaria Institutes for the study of the causes of a serious outbreak of malaria in the province of Samarkand (Middle Asia) and to devise measures for its control. A detailed analysis is given of the epidemiological situation in the Urgut district which represented the focus of the epidemic. This area is characterized by a high endemicity of malaria of all the three types the malignant tertian form being predominant. There are two efficient vectors *A. maculipennis sacharovi* and *A. superpictus* and abundant breeding places in the form of rice-fields, swamps and a network of canals. By the time the expeditions arrived and were in a position to undertake the necessary anti-malarial measures fully 100 per cent of the local population (about 40 000) had had malaria, and a high proportion among them were carriers. With the view to dealing with the existing situation and to preventing an epidemic in 1943 the following measures were adopted —

(1) Systematic anti-relapse treatment with acriquine (=mepacrine) (0.3 gm. daily in single dose) to which in the last cycle plasmocide (=pamaquin) was added. (2) chemoprophylaxis of the entire population with acriquine+plasmocide (0.3 gm. acriquine+0.04 plasmocide on two successive days followed by an interval of 5 days). (3) early detection of all acute cases of malaria and parasite-carriers and their systematic drug treatment. (4) monthly examination of the population for the detection of carriers and for observation of the indices.

The authors discuss prognosis, and, in comment MACARTHUR points out that relapse may follow a symptom free period lasting as long as 20 years. The original paper should be read by those interested in this condition.

ARANA and ARREJO (p. 908) have made ventriculographic examinations in 20 cases of cerebral cysticercosis in which the parasites were sub-tentorial. All cases were verified. The radiological findings should be studied in the original.

SELMAN (p. 816) describes a case of eosinophilia of the blood and of the cerebrospinal fluid in a patient who showed signs of meningeal irritation. The author thinks that this was probably a case of cerebral cysticercosis. A similar case is referred to by APPLEBAUM and WENBERG (p. 816).

MAZZOTTI (p. 647) gives information on cysticercosis in Mexico and again refers to the high proportion of positive results obtained in infestations with *T. saginata* by examination of the perianal region by means of swabs. This suggests the possibility of auto-infection and similar findings have been made in the case of *T. solium* but not apparently to anything like the same extent probably because the proglottides of *T. solium* do not emerge spontaneously as do those of *T. saginata* but only with the faeces.

The same author (pp. 134-388) made 108 examinations of the perianal region by means of the Graham adhesive cellulose tape method in 10 persons infested with *Taenia saginata*. Of these examinations, 85 per cent. were positive whereas with direct smear examination of faeces, the proportion was very much smaller. Eggs were also found on other areas of skin between the neck and the knees and on the underclothes. On examining the proglottides of the worm he found that the branches of the uterus communicate with the exterior when the proglottid is detached, and that disintegration is therefore not essential for expulsion of eggs.

NIRO (p. 909) thinks that Acrilan, an acridine derivative of the mepacrine type is the ideal anthelmintic for the treatment of infestation with *Taenia saginata*. Of 41 patients 34 were cured by a single treatment, and four others after more than one. Details of administration are given in the original abstract.

RIVAS *et al.* (p. 910) give details of the statistics of hydatid disease in patients treated at the Institute of Clinical Surgery Buenos Aires. The amount of information given cannot satisfactorily be summarized, and the original abstract should therefore be consulted.

BARRETT and THOMAS (p. 474) have written a long paper on pulmonary hydatid disease. It is not possible to do justice to all the points raised for which the original should be consulted, but certain statements may be noted. The presenting symptom is usually haemoptysis, but the first signs and symptoms may be due to anaphylaxis. Sudden expectoration of a large amount of clear salt-tasting fluid is diagnostic of the rupture of a simple cyst. Pulmonary hydatid cysts should never be aspirated. The parasite should be removed at the earliest possible moment. The safest way to enucleate a simple cyst is to treat it as a lung abscess, but in a selected group of cases the treatment of choice is lobectomy.

CASTRO (p. 573) discusses hydatid disease of bone. Prognosis in these cases is grave and for affected bones of the limbs, amputation is usually necessary. Hydatid disease of the spine is always fatal. HOWORTH (p. 817) also refers to the fact that treatment of hydatid cysts of bone is still unsatisfactory.

Treatment of infestations with *Hymenolepis* in children, by means of male fern given in "cycles" was found unsatisfactory by PODYAPOLSKAYA and IRAICHEVA (p. 573) who therefore experimented with other drugs given in association with male fern. Of these the most effective was methylene blue,

but yaten was also useful. For details of administration the original abstract should be consulted. GORIACHEVA (p 575) has tried this method and regards it as the best yet available he prefers it to the use of pumpkin seeds or of full doses of male fern both of which he tested.

In a study of the vitamin requirements of cestodes ADDIS and CHANDLER (p 302) found that *Hymenolepis diminuta* was markedly affected by lack of vitamins in the diet of the host if the latter was a female rat but not if it was a male (Chandler). They therefore worked with female rats and discovered that the vitamin concerned was riboflavin. If this was withheld the number and size of the infesting cestodes were smaller than in rats on full diet and the longer the vitamin had been withheld the more marked the effect. On the other hand when vitamins A D E and B were lacking the worms grew rather longer than shorter. The cestodes obtain their protein by absorption direct from the mucosa of the host not from the contents of the intestine [and presumably they obtain riboflavin in the same way].

KOUFI (p 477) reports that up to 1944 more than 70 cases of infestation with *Ixermapsisifer cubensis* had been reported usually in young children. Man is probably not the normal host and appears to be an unfavourable host but examination of a large number of mammals acari, insects and crustacea has failed to reveal the parasite

PROKOPENKO L. I. [Analysis of the Causes of the Severe Epidemic of Malaria in 1942 in Urgut District of the Samarkand Province and Measures for the Prevention of Increase of Malaria Morbidity in 1943.] *Med. Parazit. & Parasitic Dis.* Moscow 1945, 14 No 3 15-33 5 figs. [In Russian.]

The author records the results of observations made by an expedition, organized by the Moscow and Uzbek Malaria Institutes for the study of the causes of a serious outbreak of malaria in the province of Samarkand (Middle Asia) and to devise measures for its control. A detailed analysis is given of the epidemiological situation in the Urgut district which represented the focus of the epidemic. This area is characterized by a high endemicity of malaria of all the three types the malignant tertian form being predominant. There are two efficient vectors *A. maculipennis sacharovi* and *A. superpictus* and abundant breeding places in the form of rice-fields swamps and a network of canals. By the time the expeditions arrived and were in a position to undertake the necessary anti-malarial measures fully 100 per cent. of the local population (about 40 000) had had malaria, and a high proportion among the carriers. With the view to dealing with the existing situation and to preventing an epidemic in 1943 the following measures were adopted —

- (1) Systematic anti-relapse treatment with acrinone (=mepacrine) (0.5 gm. daily in single dose) to which in the last cycle plasmodicide (=pamaquin) was added.
- (2) chemoprophylaxis of the entire population with acrinone + plasmodicide (0.3 gm. acrinone + 0.04 plasmodicide on two successive days followed by an interval of 5 days).
- (3) early detection of all acute cases of malaria and parasite-carriers and their systematic drug treatment.
- (4) monthly examination of the population for the detection of carriers and for observation of the indices

These measures against the parasite in the human host were combined with anti-mosquito measures, including improvements affecting mosquito breeding places.

In undertaking all these measures the investigators realized that methods which were capable of eliminating malaria from localities with a low incidence of malaria were insufficient to cope with the infection in a highly affected focus. Nevertheless, the expeditions have succeeded in their main task—to prevent a fresh epidemic outbreak. The anti-malarial campaign resulted in a lowering of the incidence of malaria, in an absence of severe forms (coma, etc.) without fatal cases, as well as in raising the labour output of the population.

YAGUJINSKAYA, L. V. [Malaria Vectors in the Northern Part of the Urgut District, after the Observations of 1943.] *Med. Parazit. & Parasitic Dis.* Moscow 1945 v 14 No. 3, 47-56 6 figs. [In Russian.]

This paper is devoted to the results of a study of the anopheline population in the Urgut District of the Samarkand Province (Middle Asia) in which a severe outbreak of malaria occurred in 1942 (see PROKOPENKO above). A detailed description is given of the bionomics of the mosquitoes, of which the most common are *A. bifurcatus*, *A. maculipennis sacharovi* and *A. superpictus* while *A. algeriensis* and *A. pulcherrimus* occurred only singly. *A. hyrcanus* has never been found in dwellings. In view of the predominance of *A. maculipennis sacharovi* as compared with the other species during the epidemic season and on account of its known epidemiological peculiarities, this mosquito is regarded as the most important local vector of malaria. This conclusion is fully supported by the oocyst and sporozoite rates revealed by dissection.

FLOCH, H. & ABONNENC, E. Sur *A. darlingi* Root 1928 en Guyane française. Gîtes larvaires, morphologie et mœurs. [*A. darlingi* in French Guiana Breeding Places, Morphology and Habits.] *Publ. Inst. Pasteur Guyane Cayenne*. 1943 No. 63 7 pp [11 refs.] Sur le rôle de *A. darlingi* Root 1928 dans la transmission du paludisme en Guyane française. [The Role of *A. darlingi* in Malaria Transmission in French Guiana.] *Ibid* No 71 10 pp. [Summary taken from *Rev. Applied Entom.* Ser B 1946 Apr., v 34 Pt. 4 57-8.]

In the first paper data on the breeding places of *Anopheles darlingi* Root, and the house-frequenting habits of the adults are reviewed from the literature and from observations in French Guiana, where it was first recorded in 1934. Adults and larvae have since been found along the whole length of the island of Cayenne and at various places in the interior but not in the town of Cayenne which is swept by Atlantic winds. The breeding places differ greatly but are usually in open situations sheltered from wind and sometimes partly shaded from the sun. The water is acid in reaction and of low mineral content and the vegetation varied. A study of eggs laid by females from different localities in French Guiana showed that there were forms corresponding to those described by Root and by Galvão, Lane and Corrêa and an intermediate form. Sometimes they occurred alone and sometimes all three together in one batch. The adults reared from these eggs showed no differences of any consequence and the authors conclude that *A. darlingi* cannot at present be divided into varieties. *A. darlingi* represented 91 per cent. of the *Anopheles* taken in houses throughout the year but only 12 per cent. of those taken in woods.

In the second paper it is pointed out that it is most abundant in June-August when malarial endemicity is increasing and that it prefers to feed on man although it has been observed to attack fowls and ducks and is occasionally taken in traps containing horses. Data are given from the literature on its natural infection with malaria parasites in other countries. Dissection of 542 females taken in French Guiana showed seven to be infected, six with oöcysts and two with sporozoites. As the mosquitos were not from large centres of population *A. darlingi* is thought to be an important local vector in spite of this comparatively low infection rate. Of females that survived for more than four days after being fed on gametocyte carriers five out of 14 became infected with *Plasmodium falciparum* the commonest malaria parasite in French Guiana, and one out of six with *P. vivax*. In one instance infection with *P. falciparum* developed to the sporozoite stage.

FLOCH H & ABONNENC E. Sur *A. aquasalis* Curry 1932. *Publ. Inst. Pasteur Guyane* Cayenne 1943 No 68 9 pp 2 figs. *A. aquasalis* Curry 1932 et paludisme en Guyane française. Infection naturelle et infection expérimentale [Experimental and Natural Infection of *A. aquasalis* in French Guiana.] *Ibid* No 72 8 pp. [Summary taken from *Rev. Applied Entom.* Ser. B 1946 Apr v 34 Pt 4 58-9]

The species of *Anopheles* of the subseries *oswaldi* known to occur in French Guiana when these papers were written were *A. sinuatus* Senevet & Abonnenc, and *A. oswaldi* Peryassó both of which had been found only in the interior and *A. aquasalis* Curry (previously referred to as *A. tarsimaculatus* Goeldi). In view of the discovery in Venezuela of the three closely related coastal species *A. nuttall-torresii* Gabaldon, *A. rangeli* Gabaldon, Cova-García & López and *A. goeldii* Rozeboom & Gabaldon, data on the wing and tarsal colouring of these three and *A. oswaldi* and *A. aquasalis* are quoted from Gabaldon & Aguilera. However they do not make accurate differentiation possible and in order to identify with certainty the mosquitos occurring on the coast of French Guiana and referable from examination of females to *A. aquasalis* progeny were reared from several caught in nature. Examination of the adults and male hypopygia showed them to agree with *A. aquasalis*. There was considerable variation among eggs of a single batch. This is the only species of *Anopheles* occurring in houses in Cayenne but over the rest of the coast it represents 51 per cent. of the *Anopheles* taken in woods but only 6 per cent. of those taken in houses. It attacks both man and animals. Larvae were found at all seasons and occurred in fresh and brackish water. They were very adaptable surviving transfer from salt water (19 gm. sodium chloride per litre) to fresh and from fresh to salt.

Further information is given in the second paper on the occurrence of *A. aquasalis* in Cayenne, where it is found on outside walls and in dark corners of kitchens, ground floor rooms and sheds and rarely in mosquito nets. Dissection of 117 females from various parts of the colony failed to reveal any natural infection with malaria parasites. However undoubted cases of locally acquired malaria occurred in 1940 in Cayenne where there is no other *Anopheles* and experimental infection was obtained with *Plasmodium falciparum* in seven out of 30 females that survived for more than four days and with *P. vivax* in ten out of 28. In one case infection with *P. falciparum* developed to the sporozoite stage. *A. aquasalis* thus appears to be more susceptible to *P. vivax* than *A. darlingi* Root [cf. preceding abstract], but it is thought to be only a secondary vector of malaria in view of its habit of feeding indifferently on man or animals.

FLOCH H & DE LAJUDIE P Sur les divers indices endémiques du paludisme en Guyane française. [Endemic Indices of Malaria in French Guiana.] *Publ Inst Pasteur Guyane* Cayenne. 1945 No 107 10 pp. [11 refs.] [Summary taken from *Rev Applied Entom.* Ser B. 1946 Apr v 34 Pt. 4 60]

The results of recent malaria surveys made in the interior of French Guiana are given and compared with similar data for Cayenne. The spleen, parasite, and gametocyte rates were 44.24 and 7 in the interior and 12, 6 and 0.3 in Cayenne. *Plasmodium falciparum* was responsible for 85 per cent. of cases whereas 08 per cent. were attributable to *P. vivax* in 1917. A list is given of the 21 species of Anophelines known to occur in French Guiana. All have been recorded in earlier papers of this series except an unidentified species of the subgenus *Stethomyia* of *Anopheles*. *A. darlingi* Root is stated to be the principal vector of malaria, though it has not yet been taken in the regions dealt with in this survey. *A. aquasalis* Curry and *A. triannulatus* Neiva & Pinto (*bachmanni* Petrocchi) have been experimentally infected but attempts to infect *A. pessoni* Galvão & Lane, and *A. mediopunctatus* Theo failed.

MUSPRATT J On *Coelomomyces* Fungi causing High Mortality of *Anopheles gambiae* Larvae in Rhodesia. *Ann. Trop. Med. & Parasit.* 1946 Apr., v 40 No. 1 10-17 2 figs. on 1 pl.

The finding of fungal parasites of the genus *Coelomomyces* in larvae of *Anopheles gambiae* at Livingstone Northern Rhodesia, in March 1941 led the author to make further observations, until May 1945.

He was able to distinguish four types of the parasite. Type *a* was the commonest and was also the most important, for in nature it killed large numbers of larvae of *A. gambiae*. It was seen occasionally in larvae of *A. squamosus* and *A. rufipes* and once in *A. rivulorum* but it seems unlikely that the fungus seriously affects larvae of the *funestus* series. Larvae of *A. pretoriensis* became infected when transferred to an infected pool. Larvae of *A. costalis* and *A. rhodesiensis* taken from water containing infected larvae of *A. gambiae* showed no sign of fungus, and no culicine larvae (except a few *Culex simpsoni*) were infected. Laboratory-bred larvae have not yet been successfully infected.

Type *b* is rarer than type *a* and has been observed in larvae of *A. gambiae* and *A. squamosus*. Type *c* was found only in larvae of *Aedes scutophagoides*, and type *d* in the stem of a sedge (*Cyperus* sp.) but not in any mosquito larva or any other aquatic insect.

The fungus seems to be associated with the heavy dark-brown, loamy clay locally known as mopane clay. Most of the infected pools are exposed to sunlight. Infected larvae are found only during three or four months in the wet season, that is, from December onwards, and the mortality of *A. gambiae* larvae in observed pools in that period is estimated to be often as high as 85 per cent.

The author describes the appearance of the infection in the larvae and the process of germination. He is convinced that the matter is worthy of a more thorough investigation, particularly as regards the possibility of using the fungus in the biological control of *Anopheles gambiae*. H. S. Leson

RABONI C. Alcuni sintomi respiratori nell'infezione malarica primitiva. [Respiratory Symptoms in Primary Malaria.] *Riv Patol e Clin d Tubercolosi* 1944 May-June v 18 Nos 5/6 96-104 [11 refs.]

STOVHAM F V Traumatic Rupture of Large Spleens. *Indian Med. Gaz.* 1945, Nov v 80 No 11 547-11 3 figs. (1 on pl)

Malaria is by far the commonest cause of enlargement of the spleen in Asiatics in India. Rupture may be spontaneous or caused by trivial violence though more usually it is due to traffic accidents or brawls and is associated with other injuries. In the majority of cases shock and haemorrhage are so severe that the patient quickly succumbs so that probably only one in every 20 of such patients reaches hospital alive but spontaneous arrest of haemorrhage by clotting sometimes occurs even after severe damage. Delayed haemorrhage from the injured spleen is usually due to such a clot giving way. The malarial spleen unlike that in acholuric jaundice or splenic anaemia is seldom adherent to surrounding tissues. Kala azar produces large soft fragile spleens which later become firm and fibrous these may be ruptured by violence or by tearing of the capsule when spleen puncture is done. Enteric fever tumours and blood disorders are not important aetiological factors in traumatic rupture of the spleen in Asiatics.

The patient with ruptured spleen is profoundly shocked with local signs of trauma, and possibly haematuria from coincident damage to the left kidney. The abdomen becomes distended, but true rigidity is usually absent. The pulse is rapid and of poor volume, and the blood pressure is low. X ray examination which should not be done if the diagnosis can be made without it, may show raising of the left cupola of the diaphragm. Fixed dullness in the left flank with shifting dullness in the right flank (Ballance's sign) is unreliable as it depends on the size of the spleen and the amount and site of the blood clot. Liver dullness may be diminished. There is usually little or no recovery from the initial shock and the condition deteriorates progressively unless operation is undertaken promptly. A high operative mortality must be accepted if lives are to be saved and delay is justified only when the patient's condition is so low that immediate operation would be fatal or in cases where the injury occurred more than 12 hours previously and the patient's condition is stationary. The author does not think that time should be spent in resuscitation and transfusion, as these may cause further bleeding and add to the shock.

Cyclopropane is the anaesthetic of choice though chloroform with free administration of oxygen was used in the majority of the author's cases in Persia Iraq and India. Continuous pentothal administration was used in some of his later cases. A continuous intravenous infusion of saline, or of blood if available, is started at the commencement of the operation. A long mid-line incision is recommended, to which a transverse incision may be added if more room is required. As blood tends to remain fluid when shed into the peritoneal cavity the peritoneum is opened by a small incision and as much as possible of the fluid blood is sucked out by a Higginson's syringe to be added to the transfusion fluid after straining. The peritoneum is then opened widely the clots are removed and the operation completed in the usual manner. A sudden worsening of the patient's condition often occurs as the spleen is dislocated. Drainage is not employed unless there has been injury to the tail of the pancreas. Post-operative transfusion is continued till the systolic blood pressure is 100 mm. but failure to recover from shock is often seen. Simultaneous rupture of the left kidney can in most cases, be treated on conservative lines. A left pleural effusion of moderate amount is of no significance but associated injury to the chest is likely to cause trouble.

KYKER, G. C. CORMACKER, W. E. & McEWEN Mildred M. The Ultraviolet Irradiation of Quinine. *J Biol Chem.* 1946 Feb v 162 No 2, 353-61 2 figs. [16 refs.]

It is known that solutions of the cinchona alkaloids exposed to light of short wave-length undergo some change whose nature has not been definitely established. In the present investigation the photodecomposition of quinine and quinidine has been studied following irradiation with sunlight or an ultra violet lamp. The antimalarial activity of the irradiation products will be reported on at a later date. Solutions of pure material containing 5 mgm. quinine per ml were exposed to sunlight in very dilute sodium hydroxide (mixed with alcohol to retain the base in solution) in water and in different strengths of hydrochloric acid in Pyrex as well as in soft glass containers. Control samples were kept in the dark. Estimations of the amount of quinine still present were made at intervals up to 275 days in each series by three different methods. In the first two methods the turbidimetric procedure of KYKER WEBB & ANDREWS (*J Biol Chem.* 1941 v 139 551) was employed with and without previous ether extraction of base, respectively. By the third method specific optical rotation was determined. In the irradiation experiments with ultraviolet light, quartz cells which freely transmitted the wave-lengths of light absorbed by the alkaloid, served as containers. Solutions of quinine dihydrochloride and sulphate and quinidine sulphate were used for exposure. Turbidimetric and fluorimetric methods of analysis were employed. The results of irradiation with u.v. light were qualitatively similar to those obtained by exposure to sunlight but the former method was more effective in causing photodecomposition and there was only slight discoloration of the solutions. The results of analysis by the different methods did not give very concordant results. It appeared, however that the amount of decomposition depended on the pH of the solution on the concentration of alkaloid present and on the optical properties of the containers but not on the nature of the alkaloidal salt. Control tubes kept in the dark showed no discoloration or alteration in quinine content. No evidence of the chemical nature of the changes occurring was obtained.

SHIERS D. Cerebral Excitement following Mepacrine Therapy [Memoranda.] *Brit. Med J* 1946 May 18 782-3.

On three separate occasions in 1945 a soldier felt and showed signs of great mental exuberance and other emotional disturbance after taking mepacrine. There was no personal or family history of mental instability and the Wassermann reaction of his blood was negative. The symptoms are well described in the present report, which relates to the third occasion, after his admission to the Royal Masonic Hospital in December 1945 for an attack of benign tertian malaria.

He was given mepacrine 0.7 gm. daily for 2 days then 0.6 gm. daily for 7 days. Almost immediately he was seized with a feeling of extreme exhilaration and well-being. He began almost to burst with energy running instead of walking, and doing everything at top speed. His mind became choked with ideas which occurred at all times of the day and night. While many of these never reached maturity some of them resulted in the patient writing poems and creating new designs for houses and buildings. At times, too he was seized with an uncontrollable desire to cry and as a result would weep copiously although inside he felt, so he said, extremely happy.

The first occasion was in February 1945 in Assam, when he took suppressive doses of mepacrine 0.1 gm. daily with similar effects the second was in August 1945 when he had his first true attack of malaria and took mepacrine 0.2 gm. t.d.s. for 5 days in addition to quinine, and, later pamaquin again the same effects were produced during the taking of mepacrine.

He slowly recovered from this third attack on ceasing to take mepacrine and receiving phenobarbitone. [For other references to mental effects due to mepacrine (atebrin) see this *Bulletin* 1937 v 34 151 159 1938 v 35 516 1939 v 38 872 1941 v 38 337 1945 v 42, 9 253 629 784 The author refers also to ALLEN *J Med Ass Georgia* 1937 v 26 62.]

SPINKS A. & TOTTEY Mary M Studies on Synthetic Antimalarial Drugs. XV Hydrolytic Determination of Paludrine. *Ann Trop Med & Parasit* 1946 Apr v 40 No 1 101-12 7 diagrams

The method employed by the authors for the estimation of Paludrine [this *Bulletin* 1946 v 43 400] now in use for one year has been slightly modified and the time required for hydrolysis has been greatly reduced. Special precautions such as the need for clean apparatus and purity of reagents as well as points in technique are fully described. Briefly the method consists in basifying the material containing the drug with NaOH followed by extraction with a benzene-ethanol mixture. The base is taken up in N/4 hydrochloric acid and hydrolysed to *p*-chloroaniline at 20-25 lb pressure for 3-4 hours. The latter substance is then diazotized and coupled to form an azo dye and matched against a standard in a photoelectric or visual colorimeter within an hour of preparation. The procedures used with different materials such as plasma, blood urine faeces bile or tissues vary slightly in detail for these the original should be consulted. With plasma and blood the method can be used for concentrations down to 50 μ gm. per litre. With lower concentrations a modified coupling method is employed in conjunction with a Spekker absorptiometer and the sensitivity is increased 3-5 times.

A special investigation was made regarding the best conditions of hydrolysis for Paludrine and closely related compounds to *p*-chloroaniline these are embodied in the above method. It was found that Paludrine can be sufficiently hydrolysed even at 100°C. to allow of estimation if an autoclave is not available. *N*- β -sulphatoethyl-*m*-toluidine was found to be a more satisfactory coupling agent than β -1-naphthylethylenediamine. Using the former reagent the authors investigated the stability of the dye solution. The value for the extinction coefficient at the wave-length of maximal absorption was unaltered after 17 hours but there was at that time an increased absorption at lower wave-lengths. Hence the recommendation to examine the dye solutions within one hour after development of colour if a spectrophotometer is not available. Isolation of Paludrine from the urine of human subjects receiving the drug showed that the amount recovered was in fair agreement with that obtained by the hydrolytic method of estimation, and indicates that it is a suitable procedure.

J D Fulton

The result of these improvements is shown in the morbidity statistics. In 1943 the highest weekly peak of malaria incidence was equivalent to an annual rate of 410 cases per thousand. In 1944 the corresponding peak rate was 151 per thousand, and in 1945 up to the end of June it was 36 per thousand.

The paper has several illustrative examples including a detailed account of an outbreak in a Division which failed to take adequate precautions when it detrained at a very highly malarious station. The final illustration of the standard reached shows that the malaria casualties in a Corps at the highly malarious station of Venexia-Giulia were no more than those in a Corps in a non-malarious station in Austria.

[The author has an interesting story which is very much to the credit of some individuals and organizations very much to the discredit of others. It does not seem to the reviewer to set out the relevant facts adequately or in a sufficiently dispassionate manner for the reader to form an independent opinion on controversial subjects.]

KNOWLES F L & SMITH C. S. DDT Residual House Spray—a Method of Malaria Control in Rural Areas. *Pub Health Rep* Wash. 1945 Oct. 28 v 60 No. 43 1274-9

As a test of the practicability of mosquito control by the use of DDT an area of 36 square miles containing 545 houses occupied by plantation negroes on a low standard of living was chosen and 518 houses were treated with DDT the remainder being left as controls. Power-driven spray apparatus was used, and the stock solution consisted of DDT 23 per cent xylol 71 per cent. and Triton X 100 6 per cent. diluted with water to give emulsions of final strength of 5 2½ and 1 per cent. DDT. The 5 per cent. emulsion gave an actual dose of 64 mgm. per square foot, and presumably the other two doses of 32 and 12 mgm. per square foot.

The full cost of the work is not stated. Material and labour costs for each house amounted to 74 cents, while transport overhead and other charges had to be added to this, but the total cost per house was probably less than one dollar.

Efficiency of the insecticide was judged by counts of the numbers of *Anopheles quadrimaculatus* in treated and untreated houses. Spraying was completed by August 14 and the percentage reduction in treated houses was —

	5 per cent. DDT	2½ per cent. DDT	1 per cent. DDT
August 15 to September 15	97	85	63
September 15 to October 14	88	74	66
August 15 to October 14	94	81	66

GIOLIO C. L'eradicazione della malaria in Italia. [The Eradication of Malaria in Italy] *Riv di Malariologia* 1946 Feb v 25 No 1 31-5 English summary (3 lines)

BISHOP Ann & GILCHRIST Barbara M. Experiments upon the Feeding of *Aedes aegypti* through Animal Membranes with a view to applying this Method to the Chemotherapy of Malaria. *Parasitology* 1946 Jan. v 37 No. 1/2 83-100 2 figs. [25 refs.]

This paper records the results obtained from a continuation of the investigation previously reported by these authors [*this Bulletin* 1945 v 41

731] the object of which was to obtain sporozoites free from all trace of glandular tissues in order to test the action of drugs directly upon them. It can be seen from the summary of their paper quoted below that the authors have succeeded in this object and the technique they describe should be of considerable value in obtaining viable sporozoites free from glandular tissue. Later in the paper the authors state "A complete knowledge of the mode of action of any antimalarial drug which had been proved to eradicate sporozoite-induced infections in experimental animals would involve a study of its action upon sporozoites *in vitro* and upon the primary tissue phase in culture. By such *in vitro* methods it would be possible to compare the action of a drug upon the sporozoites and primary tissue phase of the species of malaria used in the experimental animal (e.g. *Plasmodium gallinaceum* in chicks) with its action upon the sporozoites and primary tissue phase of any of the species of *Plasmodium* of man. In order to approach such a study it is essential that a method should be devised whereby sporozoites can be obtained free from gland tissue and bacterial contaminants. The method in general use whereby sporozoites are obtained for injection is by dissecting out the infected glands from the mosquito and teasing them apart or grinding them up. Such a method is laborious and though suitable for infection experiments is unsuitable for the study either of the direct action of drugs upon sporozoites or for tissue culture for it is impossible to ensure that all the sporozoites are free from traces of tissue and bacterial contaminants may be present. [With this statement the reviewer is in complete agreement but, whereas the technique described by Bishop and Gilchrist is admirably adapted to fulfil the first requirement *viz.*, freedom from gland tissue it does not appear to solve the second problem that of obtaining sporozoites free from bacterial contaminants since the feeding mosquito not being sterile, will presumably introduce them when piercing the membrane with its proboscis.]

During the course of their investigation of the ejection of sporozoites by *Aedes* in the act of feeding, the authors made a series of other interesting observations which add considerably to our knowledge not only of the optimum temperature at which the food should be offered but also as regards how its nature and manner of presentation determine whether it is passed directly into the stomach or first into the diverticula.

The authors summarize their findings as follows —

1 Membranes prepared from chicken skin provide a suitable medium through which *Aedes aegypti* females may be induced to gorge.

2. Under suitable conditions the proportion of female *A. aegypti* which will gorge through membranes though more variable than when a living chick is offered is great enough for experimental purposes

"3 It is shown that the gorging reaction in *A. aegypti* is provoked by a heat gradient between the environment and the food limiting membrane.

4 The feeding reactions of *A. aegypti* towards whole blood fractions of blood and other substances have been studied. It was found that (a) whole blood and red corpuscles in saline when ingested through membranes go directly into the stomach which becomes fully distended (b) haemoglobin in plasma or distilled water is ingested to a lesser degree than whole blood or red corpuscles in saline and plasma alone is rarely ingested but all these pass to the stomach (c) sweet solutions containing glucose or honey are seldom imbibed through membranes and pass to the stomach or diverticula, but only the diverticula are fully distended.

"When offered as open drops (a) blood is seldom ingested but if ingested passes to the stomach (b) haemoglobin in plasma or water or plasma alone are very rarely ingested but pass mainly to the stomach (c) sweet solutions

infected with *P. relatum* the drug being given subcutaneously. All but one compound of each series showed activity. The most active was 2238F with a chemotherapeutic index of 1/50. Its toxicity was low and the authors believe that it merits clinical trial.
J. D. Fulton.

ZAIN H. Malariaimmunität und Rezidiventstehung unter Berücksichtigung der Endothelstudien (*Plasmodium gallinaceum*). II Mitteilung [Immunity and Relapse in regard to the Endothelial Stages of *P. gallinaceum*] *Dtsch Tropenmed Ztschr* 1944 Apr-May v 48 Nos 7/10 156-68, 2 figs. [19 refs.]

The author has shown that the serum of latently infected chickens which have been subjected to repeated injections of chicken blood heavily infected with *P. gallinaceum* contains antibodies in sufficient amount to give rise to a passive immunity in chickens which have been injected with it. This passive immunity is exemplified by the delay in the appearance of parasites in the blood after inoculation, and the lowering of the intensity and the curtailment of the resulting infection. When such immunized chickens are subjected to superinfection, not only is there a failure of parasitic forms. Similarly but there is also no new development of exoerythrocytic forms. Similarly when a blood relapse is caused by splenectomy this is not associated with the reappearance of exoerythrocytic forms. It seems clear therefore that the immune bodies in the serum are directed against both the erythrocytic and exoerythrocytic stages of the parasite. The question arises as to whether there is only one immune body capable of checking the development of both stages of the parasite or whether two distinct bodies are involved.

To settle this question, an attempt was made to liberate into the blood stream any immune bodies which might exist in the reticulo-endothelial cells, and which might be supposed to be immune bodies having a special action on the exoerythrocytic stages which develop in these cells. Accordingly chickens with latent malarial infection whose blood serum was shown to be devoid of any immunizing properties, were subjected to repeated injections of manganese chloride. This had the effect of conferring on the blood immunizing properties which it did not previously possess, as a result it is concluded, of the liberation of immune bodies from the reticulo-endothelial cells. These properties differed in no way from those possessed by the serum of chickens immunized by the repeated injection of heavily infected blood as in the first experiments. It seems clear therefore that the immune bodies produced by the stimulus of erythrocytic forms of the parasite are not different from those appearing in endothelial cells under the stimulus of the exoerythrocytic stages of development. As exoerythrocytic forms occur in the endothelial cells of the blood vessels as well as in cells of the reticulo-endothelial system in the tissues the further question arises—are the parasites in these two situations identical as regards their susceptibility to the immune substances in the blood, or are there differences between them which might have some bearing on the fact that sporozoit-induced malaria in man is liable to repeated relapse while blood-inoculated malaria is not?

WOLFSON, FRANK. Effect of Preservation by Freezing upon the Virulence of *Plasmodium* for Ducks. *Amer J Hyg* 1945 Sept., v 42, No. 2, 155-66

The paper describes the results of experiments designed to test the degree of survival of three species of avian malarial parasite (*P. cathemerium*, *P. lophurae* and *P. risatum*) when blood taken from infected ducks is subjected to rapid freezing and, following storage at -76°C . for periods varying from two hours to

one year to rapid thawing at 42°C. The effect of these procedures was estimated by the study of Giemsa stained films of the stored blood and by the results of inoculation into young ducks. It was found that the proportion of erythrocytes and probably of parasites which survived varied directly with the proportion of parasitized erythrocytes in the sample of blood before freezing. This is contrary to the findings of MANWELL and EDGETT in similar experiments. They stated that the greater the number of parasites in the blood the greater was the proportion of erythrocytes destroyed [this *Bulletin* 1944 v 41 189]. The author of the present paper found that the preservation of *P. cathemerium* had no effect on the length of the prepatent period, the day on which the peak of parasitaemia occurred and the degree of the parasitaemia at the peak. The three parasites investigated showed no appreciable differences in their ability to survive as judged by the number of erythrocytes and parasites surviving, but the results of the infectivity tests indicated that *P. cathemerium* survived more regularly than the other two parasites. It was noted that ducks inoculated from those infected from the frozen material developed a lower degree of parasitaemia than did controls but that from one to three subsequent passages were usually sufficient to restore the virulence of the parasite.

MARVIN H. N. & RIGDON R. H. Terminal Hypoglycaemia in Ducks with Malaria. *Amer J Hyg* 1945 Sept. v 42 No 2 174-8 2 figs. [12 refs.]

A study of the blood sugar level in ducks infected with *Plasmodium lophurae* has shown that there is an increasing hypoglycaemia following the peak of infection. At the time of death, usually 8 hours after the peak, there may be a 60 per cent. reduction in the blood sugar. As malarial parasites require relatively large amounts of sugar for their development *in vitro* it seems reasonable to suppose that the fall in the parasitaemia is the direct result of the hypoglycaemia. This is supported by the observations made by HEGNER and MACDOUGALL [this *Bulletin* 1926 v 23 863] that a hypoglycaemia caused by injections of insulin brought about a decrease of malarial parasites in canaries. According to the authors the course of events in these malarial infections in ducks is an anaemia caused by destruction of erythrocytes leading to anaemia. This damages the liver with impairment of hepatic function and hypoglycaemia which contributes to the death of the host in spite of the fact that it brings about a decrease in the parasitaemia.

C. M. Wenyon

RIGDON R. H. *Plasmodium lophurae* Infection of the Chick Embryo. *Amer J Hyg* 1945 Sept. v 42, No 2 189-94

The author has studied the results of inoculation of *Plasmodium lophurae* from infected ducks and chicks into developing chicken eggs. The results indicate that infection will not occur in embryos when infected blood is injected into the yolk sac. Infections on the other hand, will result if the blood is inoculated directly into the embryo. If such inoculated embryos are allowed to hatch, it will be found that usually few if any parasites are present in the blood. In only one chick was there a high grade parasitaemia at the time of hatching. More often parasites first appeared in the peripheral blood on the third or fourth day after hatching and the degree of the resulting parasitaemia varied. Some chicks showed only a few parasites on several days while others developed a high degree of parasitaemia. It appears from this study that the chick embryo is not such a suitable host for *P. lophurae* as the young chick. Some unknown factor in the embryo appears to hinder its development. No significant pathological lesions were observed in the infected embryos except

MARTINS A. V., VERSIANI V. & TUPINAMBÁ, A. A. Estudos sobre a moléstia de Chagas no estado de Minas Gerais. I. Estudo epidemiológico de um foco da moléstia no município de Jaboticatubas. [Chagas's Disease in the State of Minas Gerais. I. Epidemiological Study of a Focus in Jaboticatubas.] *Arquivos do Inst. Químico-Biol Estado de Minas Gerais* 1945 v 1 51-61 12 figs. on 9 pls. English summary (10 lines)

This investigation was carried out at the end of 1939 and the beginning of 1940 and was cut short by the death of Evandro Chagas. Jaboticatubas is a small municipality in central Minas Gerais, some 70 kilometres from the capital. The inhabitants live in hovels (*casas*) some with mud walls, made of woven twigs and laths the interstices being filled with earth, others with uncelled tile roofs. The district is fairly dry and relatively healthy there is no malaria, but infestation with *Ascaris lumbricoides* is very common. The inhabitants live by cultivating millet and manioc, and, to a small extent on the lower levels rice.

Of 18 mud huts investigated, 15 were harbouring the vector of *T. cruzi* and the insects were found infected in 9 of them. Only one of the tiled huts was infested and the insect caught was positive for *T. cruzi*. Of a total of 146 inhabitants 33 were found positive by examination of thick drops and by xenodiagnostic methods. In 10 of the 18 mud huts the inhabitants were positive, and in 7 of the tiled huts. In the former the inhabitants totalled 102, and 23 of them were infected in the latter 44 and 10 were infected. Of the 33 infected, 15 were in the second decade none was under one year of age. There was no appreciable difference as regards sex 14 of 66 males were infected and 19 of 80 females.

Animals were also examined. Of the domestic animals 5 of 22 dogs and 2 of 7 cats were infected all 7 were in the mud huts none in the tiled. Forty wild animals belonging to 9 species were examined, but only two armadillos (*Dasypus novemcinctus*) were positive. Of 124 *Parastomylus megistus* examined 36 were positive and 7 of 51 *Triatoma sordida* that is 43 were positive out of a total of 175 vectors examined. There are 12 photographs showing clearly the terrain and the inhabitants.

MARTINS A. V., VERSIANI V. & TUPINAMBÁ, A. A. Estudos sobre a moléstia de Chagas no estado de Minas Gerais. II. Sobre 156 xenodiagnósticos feitos em Belo Horizonte. [Chagas's Disease in the State of Minas Gerais. II. One Hundred and Fifty-Six Xenodiagnostic Tests carried out in Belo Horizonte.] *Arquivos do Inst. Químico-Biol Estado de Minas Gerais* 1945 v 1 63-70 1 folding map English summary

Xenodiagnosis has proved to be the most reliable test in chronic cases of Chagas's disease. The subjects selected for the test were attending the hospitals and clinics in Belo Horizonte Minas Gerais Brazil. The investigation was carried out at intervals between April 1939 and August 1942, and the subjects chosen came under one or other of four categories i. With myocarditis of undetermined cause ii. With mal de engasgo (mega-oesophagus) [see this Bulletin 1921 v 18 301 1927 v 24 830]. iii. With goitre with or without cretinism. iv. Those with no definite symptoms but presenting themselves for examination either because they lived in places where Chagas's disease is endemic, or because others of their families were suffering from it.

The insects used were *P. megistus* *T. infestans* and *T. cruzi* reared in the laboratory. They were examined 40 days after their feeding on the patient their rectal contents taken by pipette and later their whole bodies were dissected and examined.

Generally one test only was made with each patient. The results were as follows. Of 63 in Group i (myocarditis patients) 23 were positive of 48 in Group ii (mega-oesophagus) 22 positive of 28 in Group iii (goitre) 5 positive and all came from parts of the State where infected bugs had been captured. Of Group iv one was positive out of 17. In all 51 were positive among the 156 tested. The distribution in the 32 municipalities is given but this is not of much value since none gave more than 3 and 18 had only one each. 9 had two.

VIZCARRONDO R. O. Notas sobre la enfermedad de chagas y en particular en el Estado Aragua. [Notes on Chagas's Disease, especially in the State of Aragua.] *Rev Sanidad y Asistencia Social* Caracas. 1945 Oct.-Dec. v 10 Nos 5/6 635-66 1 map & 15 figs. on 10 pls [41 refs.]

As usual in articles on Chagas's disease the opening pages repeat the history of Carlos Chagas's early work, the vectors of infection and the modes of conveyance. After this the author shows on a sketch map the places where infected *Rhodnius* were found but in 7 chief districts only 107 insects were examined 48 were found positive. Next examinations were made of inhabitants of the town of Maracay. Eight per cent. of schoolchildren had palpable spleens and 6 per cent. harboured malaria parasites the corresponding figures for soldiers were 13 and 11 per cent. and for various people in the town 4 and 6 per cent. [These figures convey little if any useful information since in no case is the number examined stated.] Then follow descriptions of three cases. The first is called a case of lymphatic leukaemia with leucopenia seemingly because there was a relative lymphocytosis. Red corpuscles numbered 1,300,000 white 1,600 per cmm. lymphocytes 42 per cent. Ova of *Necator americanus* and of *Trichuris trichiura* were found in the stools and the case would appear to have been one of helminthic infestation with secondary anaemia. Malaria parasites were repeatedly looked for but in vain. The second was a case of myelocytic leukaemia the third had some degree of anaemia and xenodiagnosis proved infection by *T. cruzi*. Other notes include a chemical analysis of the water of Lake Tacarigua made in 1941 and research on the use of DDT its pharmacological action and its compatibles.

LIEM S. D. & VAN THIEL, P. H. The Complement-Fixation Test for Chagas' Disease employing a Dried Culture Antigen. *Acta Leidensia (Scholae Med Tropicae)* 1940-41 v 15-16 259-74

Tests of a dried antigen prepared from a culture of trypanosomes on horse blood glucose agar [see LIEM this *Bulletin* 1938 v 35 719] are described. The strain of trypanosomes was isolated at Hamburg in 1935 by MALAMOS [*ibid* 1935 v 32 718] from *Macaca irus* [*Macacus cynomolgus*] recently arrived from the Netherlands East Indies. It was identified by Malamos as *T. cruzi*. The authors received the strain in the bug *Triatoma infestans* in 1936.

The sera of rabbits immunized by intravenous injections of cultures of the trypanosome and the sera of dogs infected with it were used for antibody while guinea-pig serum provided the complement. The sera of two persons in South America who were suffering from Chagas's disease were sent to the authors at Leiden, Holland, and gave negative results in the complement fixation test but owing to the time taken in transit no conclusion can be drawn from the tests. As a control, 385 sera of patients in Holland suffering from various diseases were tested. 4 out of 146 Wassermann positive sera were positive and 4 out of 6 sera of patients suffering from chancroid were also positive but all the other sera were negative.

The authors conclude that the dry antigen used, which is sealed in vacuo in ampoules and kept in the refrigerator is better than other antigens, and they recommend its trial in known cases of Chagas's disease in South America.

MAZZA, S. BASSO G. & BASSO R. Investigaciones sobre enfermedad de Chagas. Contribución para la terapéutica de la enfermedad de Chagas. Últimos ensayos quimioterápicos M.3024, I.C.I. Aplicación de penicilina. [Studies on Chagas's Disease. Treatment with M.3024 and with Penicillin.] Universidad Buenos Aires Misión de Estudios de Patología Regional Argentina (Jujuy) Publicación No 70 1945 81 pp. 36 figs. [Bibliography.]

The authors begin by reviewing the literature on the use of 7602 (Ac) Bayer in Chagas's disease and follow this by a record of cases in which they have used M.3024 the British equivalent of the Bayer preparation. Several of these cases are detailed. The initial dose is 7-12 mgm. per kilo body-weight usually 0.15 gm. 2-4 cc. were generally given at 5-7-day intervals, the second dose being double that of the first. Improvement was rapid and the external signs (swelling of the eyelids and face) disappeared in 5-12 days.

Penicillin was then tried. It was given by intramuscular injection 2 cc. every 3 hours containing 5 000 Oxford units per cc. Again several cases are detailed and the total amount given was about 400 000-500 000 units. Both local and systemic symptoms improved. [The authors do not attempt to discuss the relative values of these forms of treatment. It would be instructive if they would present parallel series of cases and a reasoned discussion of the results observed.]

LEISHMANIASIS

GEROVNIKOV A. A. Incidence of Visceral Leishmaniasis in Samarkand during 20 Years (1924-1944). *Méd. Parasit. & Parasitic Dis.* Moscow 1945 v 14 No. 3 88-9 [In Russian.]

The author analyses the incidence of visceral leishmaniasis in Samarkand (Middle Asia) from 1924 to 1944. During this period the total number of recorded human cases was 921 which were fairly evenly distributed from year to year in spite of a progressive increase in the population in the course of 20 years. Thus, the absolute growth of the population was not accompanied by a proportional rise in the incidence of kala azar. A comparison of the figures for the incidence of leishmaniasis in man and in dogs for 11 years (1933-43) shows that there is a complete parallelism between the two diseases the fluctuation in the incidence of human disease corresponding to that in the canine and being correlated not only with the percentage of infected dogs but also with the total number of dogs in the town.

As regards incidence in age-groups, the great majority of cases (54-74 per cent. of all cases) occur in children between the ages of one and five and chiefly from one to three. Children older than ten years are rarely affected, while during the last nine years there has not been a single case of infection in persons older than 18 years.

It is concluded that the stabilization of the incidence of kala azar in Samarkand is due to the systematic measures adopted for the early diagnosis and treatment of the disease as well as to the elimination of infected dogs. The latter are regarded as constituting the chief epidemiological danger.

NAJERA ANGULO L. Observaciones sobre el ciclo evolutivo de *Leishmania infantum* Nicolle 1908 [The Developmental Cycle of *Leishmania infantum*] Reprinted from *Rev Ibérica de Parasit* Granada. (Tomo extraordinario) 1945 Mar 181-98 1 fig & 1 coloured pl. [22 refs.]

In this paper the author upholds the view as others have done that the parasite of infantile kala azar may reproduce by schizogony. The majority of observers believe however that the appearances of schizogony are due to the presence of leishmania in detached portions of the cytoplasm of infected macrophages in which the outlines are not visible owing to bad fixation or degenerative changes. In the present paper the author suggests that certain granular cytoplasmic bodies seen especially in smears of the bone marrow of cases of infantile kala azar and which contain no semblance of the characteristic leishmania nuclei and kinetoplasts are actually young schizonts. They are described as increasing in size till they are larger than a red blood corpuscle. Associated with this growth there are gradually formed in the cytoplasm presumably from the granules a series of nuclei and kinetoplasts. Finally by separation of cytoplasm around the nuclei and kinetoplasts a varying number of leishmania are formed, which lie in a cyst membrane the remains of the supposed schizont. These leishmania are liberated by rupture of the cyst and either commence the process again or are phagocyted by the macrophages. These phagocyted leishmania may fill the macrophages and have hitherto been regarded as parasitic in these cells. According to the author they are destined for phagocytic destruction. What is perhaps most remarkable is the author's opinion that this type of development is peculiar to *Leishmania infantum* and will account for the differences in the diseases caused by this parasite and *L. donovani*. The paper is illustrated by black and white text figures and a coloured plate which the reviewer has to admit he finds unconvincing.

ADLER, S. The Sandflies of Cyprus (Diptera) *Bull Entom Res* 1946 Feb v 36 Pt. 4 497-511 6 text figs & 4 figs. on 1 pl. [24 refs]

Ten species of *Phlebotomus* were collected in Cyprus during August and September 1944. They were *P. papatasi sergenti alexandri perniciosus* var *tobbi chinensis perfiliensis larroussesi parroti arisi* sp. n. and *fallax* var *cypricola* var. nov.

Taxonomy of these species is discussed and the new forms are described and illustrated. Keys to both sexes are provided.

The incidence of human visceral leishmaniasis in the island is unknown though the first case was recorded in 1935. Canine kala azar is not rare. The author considers that *P. perniciosus* var *tobbi* and a race of *P. chinensis* should be investigated as possible vectors.

CHATTERJEE H. N. Postmortem Femoral Bone Marrow Studies of Kala-Azar
Trans Roy Soc. Trop Med. & Hyg. 1946 Feb., v 39 No. 4 315-20
 4 figs. on 1 pl. (13 refs.)

An examination of the femoral bone marrow from fatal cases of kala azar has shown that in an acute case there was almost complete absorption and replacement of the fat cells. There was a total absence of the degenerative changes met with in later stages of the disease the general structure of the marrow being made up of large numbers of clasmatocytes and cells of the myeloblastic series. Of the clasmatocytes about 30 per cent. contained leishmania. In later subacute cases the marrow reddish in colour was tougher than normal. The total number of cells was diminished particularly in certain areas which contained few cells and presented a homogeneous ground-glass-like appearance. Of the clasmatocytes present, nearly all contained leishmania. The ground-glass-like material was the result of precipitation of fine fibrils in the fat vacuoles. In addition there was some increase in the argyrophil reticular fibres. In later chronic cases there was a further reduction in the number of cells, those of the myeloid series being remarkably diminished. The reticulo-endothelial cells of clasmatocytes were the most conspicuous cells. They possessed a large amount of amoeboid and branched protoplasm and were packed with parasites. The fibrils noted in the subacute cases were more pronounced, while there was a marked proliferation of the argyrophil reticular fibres. The author concludes that the progressive degeneration of the marrow and the cellular changes will explain the leucopenia and neutropenia and increasing anaemia which are characteristic of kala azar. C M Wenyon.

GELLHORN A. VAN DYKE, H. B. PYLE W. J & TUPIKOVA, N. A. Amyloidosis in Hamsters with Leishmaniasis. *Proc Soc. Exper Biol. & Med.* 1946 Jan. v 61 No. 1 25-30 3 figs.

In a recent paper GOODWIN [this Bulletin 1946 v 43 318] has shown that hamsters infected with *Leishmania donovani* may suffer from oedema nephritis proteinuria and depression of the level of the plasma proteins. The authors of the present paper confirm these findings and give the additional information that, on and after the 46th day of the infection an increasing degree of amyloidosis occurs in various organs more particularly in the kidneys and suprarenals. At the same time it was noted that though the globulin level in the blood remained normal the albumin level fell considerably so that the A/G ratio was significantly lowered in the infected animals. This decrease in the blood albumin was correlated with the passage through the kidneys of increasing amounts of albumin due to the amyloid degeneration of the glomeruli and to a lesser extent of the tubules. At the same time there was a lowering of the colloid osmotic pressure of the plasma leading to the escape of excessive amounts of fluid into the tissues and to the development of oedema and anasarca. The authors do not believe that failure of the synthesis of plasma albumin is responsible to any important extent for the lowering of the percentage of this protein in the plasma. C M Wenyon

SEN GUPTA, P. C. 4 4 Diamidino-Diphenyl-Ether in the Treatment of Indian Kala Azar. *Indian Med. Gaz.* 1945 Oct. v 80 No. 10 495-8.

In an earlier communication [this Bulletin 1945 v 42, 264] the author reported upon the treatment of 16 cases of kala azar with this drug, which has been given the proprietary name of phenamidine (M & B 736). In the present paper these 16 cases together with 14 others similarly treated are considered. The ages varied from 1 to 80 years and the duration of illness from

1 month to 2 years. The drug was administered intravenously in 1 per cent solution the usual course being one injection each day for 10 days. This was followed by a second course after a 10-day interval. The initial dose for an adult was 25 mgm. This was increased by 25 mgm. daily till a dose of 1 mgm per pound of body weight was reached. The mean total dose for an ordinary case worked out at $1.73 \text{ gm.} \pm 0.477 \text{ gm.}$ or for 100 pounds of body weight, $1.854 \pm 0.396 \text{ gm.}$ Of the 30 patients 24 completed the treatment and were discharged as clinically cured. Six months later 21 of these were traced. Sixteen were in good health and were considered cured, while five had relapsed. The permanent cure rate is given as 64 ± 19 per cent. It is concluded that the drug is inferior to the most effective pentavalent antimonials or to diaminodiphenylstilbene. On the other hand it is non-toxic and should be useful in cases in which antimonials are contraindicated as for instance when the complication of grave pulmonary tuberculosis exists.

WIEN R. Excretion of Stilbamidine *Trans Roy Soc Trop Med & Hyg*
1946 Apr v 39 No 5 455-8

Stilbamidine was injected subcutaneously into rats in doses of 1 to 10 mgm. per kgm every day for 15 days and the excretion in the urine was measured by means of the fluorescence (which measures the unchanged molecule) and by a glyoxal reaction (which measures both the unchanged and slightly changed molecule). With a daily dose of 1 mgm. per kgm the percentage excretion of the day's dose was 1.6 on the 5th day 1.8 on the 10th day and 2.5 on the 15th day when measured by the fluorescence and 42 on the 5th day 52 on the 10th and 59 on the 15th day when measured by the glyoxal method. A large proportion of stilbamidine was presumably metabolized and excreted in a non-fluorescent form. Similar results were obtained when the excretion of 2-amino-4,4-diamidinostilbene was studied. This compound is closely similar to stilbamidine (4,4-diamidinostilbene) but it can be estimated by diazotization as well as by fluorescence. The greater the number of injections of stilbamidine which had been given the higher was the proportion of the daily dose excreted. Conversely the larger the daily dose the smaller was the proportion excreted, presumably the kidney could eliminate only a limited amount of the compound. The higher doses (5-10 mgm. per kgm.) were toxic, and some of the animals died.

PACKCHANIAN A. Leishmaniasis. The Cultivation of *Leishmania tropica* from Two American Soldiers who had returned to the United States from the Near East *J Amer Med Ass* 1945 Oct. 20 v 129 No 8 544-7 [Refs. in footnotes]

The paper is based on two cases of oriental sore in soldiers returned to the U.S.A. from Iran. In both cases parasites were demonstrated in the lesions while cultures in the water of condensation of blood agar medium were obtained. Attention is called to this occurrence of exogenous cases of oriental sore in the U.S.A. and a warning is issued that further cases of the kind may be expected. The author advises the making of cultures in all suspected cases for if a positive culture is obtained there is no danger of confusing the flagellates with other organisms whereas in smears from the sore inexperienced observers may confuse yeasts with leishmania and in consequence make an erroneous diagnosis.

C M Wemyss

KOJEVNIKOV P V [The Absence of Cross-Immunity between the Two Types of Cutaneous Leishmaniasis.] *Med Parasit & Parasitic Dis* Moscow 1945 v 14 No 3 82-8. [In Russian.]

It is well known that cutaneous leishmaniasis usually conveys a lasting immunity though cases of reinfection are also known thus among 1,894 case histories in Ashkhabad the author found 96 (4.5 per cent.) records of repeated infections. Cases of reinfection are especially liable to occur on transfer from one endemic area to another. In 1940 the author established the presence in Middle Asia of two types of oriental sore the dry urban form and the moist rural form [see this *Bulletin* 1944 v 41 331]. On analysing the above 96 cases of reinfection it was found that 18 patients originally had the first form, later acquiring the second form while in four cases the sequence was reversed whereas in 62 patients the type of the original infection remained unknown. Moreover in some cases the two types of sores developed independently in the same subject. It was suggested that there was no cross-immunity between the two types of cutaneous leishmaniasis.

The author records further observations confirming this view. In 1942 a large group of schoolchildren from Ashkhabad, where the dry variety of oriental sore is prevalent spent one to two months on field works in an endemic area of the moist variety with the result that 59 per cent of the children acquired an infection with the latter type of the disease. It was ascertained that of 300 children, 49 had formerly suffered from the dry form of the disease 10 had been vaccinated with this variety while two had previously had sores of the moist type. In 44 children there was circumstantial evidence of previous infection with the dry form, whereas in 45 no data were available. In 55 per cent of the cases a previous infection with oriental sore of the dry type failed to protect against infection with sores of the moist type. However a previous infection with the former type reduced the severity of the second infection pointing to some degree of group immunity. Further confirmation of the strain-specificity of the immunity was provided by the results of vaccination inoculation of cultures of leishmania isolated from sores of one type protected against infection with the homologous sores but not against heterologous sores. Finally there is evidence that in rare cases, there may be reinfection after five to nine years with sores of the same type as in the primary infection.

It is concluded that cross-immunity between the two types of oriental sore absent or only slightly developed and that the course of infection with a homologous type is milder than in the primary disease. In prophylactic vaccination against cutaneous leishmaniasis either the strain used should correspond to the type of sore prevalent in the locality where the vaccinated person proposes to reside or strains of both types should be used.

FILATOV V P Tissue Therapy in Cutaneous Leishmaniasis. *Amer Rev Soviet Med* 1945 Aug v 2 No 6 484-90 14 figs. on 2 pls

Under the term tissue therapy the author describes a procedure which he states is based on a new principle in medicine. He holds that animal and plant tissues when preserved under adverse conditions generate biogenic substances which stimulate healing and regeneration when they are introduced into the body. The introduction may be made by various methods—grafting, implantation, subcutaneous and intramuscular injection, surface applications, rectal injections. The author claims that a great many diseases have been successfully treated by this method among these cutaneous leishmaniasis is

specially mentioned in this paper. This has been treated by grafting on to areas from which a piece of healthy skin has been removed a similar piece of skin which had been removed from a cadaver and had been preserved under refrigeration for a week. Within a few days of the skin graftings which are made at points distant from the sores changes occur in the leishmania ulcers and healing takes place in two to three months with a minimum of scarring. Similar results were obtained by grafting the preserved skin of the rabbit or by the injection of extract of the leaves of the aloe which had been preserved in the dark. The author concludes that the cases described in the paper demonstrate the powerful effect which tissue therapy exerts in cutaneous leishmaniasis. Grafting of conserved skin and subcutaneous injection of an extract of preserved aloe leaves are equally effective. Tissue therapy acts by virtue of systemic stimulation independently of the aetiology of an ulcerative process. Thus tuberculous ulcers, syphilitic ulcers and leishmania ulcers are equally benefited. The paper is illustrated by a series of photographs showing the results of treatment of leishmania ulcers by the author's method.

C. M. Wenyon

FEVERS OF THE TYPHUS GROUP

ROY B. C. Typhus Fever with special reference to its Incidence in India
J Indian Med Ass 1946 Feb. v 15 No 5 135-46 149 2 figs. (1 map)
[89 refs.]

In this clinical description the author uses the name typhus fever as synonymous with the term fevers of the typhus group and he seems to favour the unconventional view that all the fevers of the group in India are louse-borne. He states for example that it has not been proved of course that Indian typhus is louse-borne but there is no reason to suppose the contrary. Blood of various arthropod vectors was examined but no definite clue could be obtained.

The paper contains a good deal of useful information including a table showing the localities in India from which cases have been reported up to 1943 also the vector suggested in each group of cases and the serological type when this has been recorded. There is a bibliography which gives references to most of the articles dealing with typhus-group fevers in India up to 1943 but no reference is made to the important observations published since that date.

PLOTZ H. WERTMAN K. & BENNETT B. L. Identification of Rickettsial Agents Isolated in Guinea Pigs by means of Specific Complement Fixation
Proc Soc Exper Biol & Med 1946 Jan. v 61 No 1 76-81

The experiments described in this paper show that the complement-fixation test as applied by the authors is the most reliable method of differentiating the rickettsiae of murine typhus, epidemic typhus and Rocky Mountain spotted fever in guinea-pigs. The special proviso is that the antigens employed must be purified by washing to remove the common antigen.

The results of the experiments are shown in three tables from which the following analysis has been prepared to show the trend of the responses observed in three lots of guinea-pigs each of which received intraperitoneal injections of equal doses of one of the strains of rickettsiae. The data refer to the animals that survived all causes of death long enough to allow the fixation test to be carried out about four weeks after inoculation.

Strain of Infection	In cuba tion (days)	Fever (days)	Scrotal Reaction		Complement-fixation titre		
			Pre- sent	Ab- sent	Epi- demic	Murine	R.M.S.F
Murine (Wilmington)	3-7	0-7	31	11	0-80	80-640	0
Epidemic (Breml)	5-19	0-10	4	35	80-640	0-40	0
R.M. spotted fever (mild strain)	2-6	2-9	No mention		0	0	320-640

Some cross-fixation occurred in many of the guinea-pigs inoculated with epidemic and murine strains but in every case the titre with the homologous antigen was at least four times as high as with the heterologous. There was no cross-fixation between Rocky Mountain spotted fever and the other two infections.

Two of the 42 guinea-pigs inoculated with murine rickettsiae had no febrile reaction but their sera yielded homologous fixation titres of 1-160 and 1-320 and immunity tests showed that they had reacted with inapparent infections.

Six of the 39 guinea-pigs infected with epidemic rickettsiae had no febrile reaction one of these had a fixation titre of 1-160 and was proved to be immune the other five remained negative to the test and were non-immune so they must have escaped infection.

The consistent reliability of the complement fixation test in the differential diagnosis of the type of infection in inoculated guinea-pigs is in striking contrast with the uncertain indications yielded by the febrile and scrotal reactions.

[Further investigation will be needed to show whether all strains of these types of rickettsiae can be expected to give equally consistent responses.]

John W D Megaw

GROUP V & DOVONICK R. On the Specificity of Epidemic and Murine Typhus. *Science* 1946 Mar 15 330-31

The existence of specific differences between epidemic and murine typhus fevers has been shown by the following experiments.

Two groups of young Swiss-white-mice were vaccinated one group with epidemic vaccine of the Breml strain, and the other with murine vaccine of the Wilmington strain. Fourteen days later half of the mice of each group were challenged by lethal doses of toxins obtained from epidemic rickettsiae and the other half by corresponding doses of murine toxins. The results observed 18 hours later were —(1) Of 23 mice vaccinated by epidemic vaccine 20 survived the dose of epidemic toxin whereas all the 23 vaccinated by the same vaccine and challenged by murine toxin died. (2) Correspondingly of 23 mice vaccinated by murine vaccine 22 survived the dose of murine toxin, whereas all the 23 vaccinated by murine vaccine and challenged by epidemic toxin died.

These findings are opposed to those reported by FITZPATRICK, who obtained results suggesting that the epidemic and murine toxic factors are identical [this *Bulletin* 1945 v 42, 783]

John W D Megaw

DICK J C. Notes on the Weil-Felix Reaction in Typhus Fever and other Diseases. *J Path & Bact* 1946 Jan. v 58 No. 1 21-30 [24 refs]

Between March 1942 and February 1944 505 Weil-Felix tests were carried out on 308 cases of various fevers including 80 of typhus in a hospital in the

Middle East Standard R.A.M.C. suspensions and Dreyer's tubes were used. The results were read after overnight incubation at 37°C. The end point was the last tube in which a definite ring of particles could be obtained by rotation and seen by the naked eye at the neck of the tube with examination in a strong light against a dark background. In these conditions within the first 10 days of illness a titre of 1-240 was regarded as slightly suggestive of typhus and one of 1-480 as very suggestive. At any stage a titre over 1-480 was considered as definitely positive.

At first all the three usual strains of *Proteus* were used but it was soon found that non-specific reactions with OXA were relatively common at titres of 1-480 and even titres of 1-960 with this strain could not be regarded as definitely positive so that in the absence of evidence of the existence of mite borne typhus in the area the OXA test was discarded.

In 68 of the 80 cases of typhus fever rickettsia-agglutination tests were carried out by VAN ROOYEN who diagnosed 21 of them as epidemic (house borne) 36 murine (flea-borne) and 11 as incapable of being differentiated by the test.

Among the 80 cases of typhus the Weil-Felix titre (OX19 or OX2 or both) rose to above 1-480 in 73 and to 1-480 in the remaining seven. The earliest definitely positive reaction occurred on the 6th day and in observations made after the 10th day the titre fell below 1-480 in only two cases both of which yielded titres above 1-480 at a later date.

The titre with OX19 was usually higher than that with OX2 but in six murine cases and one other the positive titre was reached with OX2 and not with OX19.

No evidence clinical or bacteriological could be found to warrant the claim that the cases of OX2 agglutination studied were due to tick borne infection. [The possibility that tick typhus might occur in M.E.F. and Egypt was suggested by the reviewer who stated that it would be surprising if the tick borne disease were absent from the area which included Egypt, Palestine and parts of Iraq and Persia (this *Bulletin* 1945 v 42 195)].

Among 26 cases of typhoid fever titres of 1-120 or over were observed in nine patients and in three of these the titre with OX2 reached 1-240. Among 28 cases of paratyphoid A or B a titre of 1-240 was reached in eight. In one patient with paratyphoid B a double infection was considered possible because the titre with OX19 and OX2 was 1-960 on the 14th and 16th days and by the 90th day the OX19 titre was 1-60 and the OX2 titre was 1-30. All the other evidence however was opposed to the existence of typhus infection in this case. In two cases of paratyphoid A titres of 1-240 with OX19 and 1-120 with OX2 were observed on the 5th and 8th days respectively but by the 27th and 32nd days the titres had fallen to 1-30. Rising titre agglutinations at low levels occurred with OX2 in typhoid and with OX19 and OX2 in paratyphoid in some cases so the author advises that care should be exercised in the interpretation of such reactions.

In 166 cases of fevers other than typhus and the enteric group 268 Weil-Felix tests were carried out at various stages. In 22 cases no agglutination occurred in 80 the maximum titres with OX19 or OX2 or both were 1-30 or 1-60 in 52 the maximum titre was 1-120 in 10 it was 1-240 and in two it was 1-480. Titres of 1-60 or under are regarded as insignificant. In most of the non specific agglutinations with titres of 1-120 or over the highest titre was usually observed early and a fall soon occurred but sometimes the titre remained fairly constant and in a few cases a rising titre was observed. Non specific agglutination was more frequent with OX2 than with OX19.

Among six cases of measles three reacted at 1-120 with OX2 and a fourth had a titre of 1-480 up to the 7th day after which the titre fell. One case of

common cold gave a titre of 1-480 (OY2) and two of influenzal broncho-pneumonia reached 1-240 (OY2). In two of eight cases of infective hepatitis a titre of 1-120 (OY19 and OX2) was observed in the later stages. In several cases of pyrexia of unknown origin repeated tests were made the titre never arose above 1-250. In a case of lymphadenoma the findings were confusing as can be seen from the table below —

Day of disease	Agglutination titres				
	OX19	OY2	OXK	Epidemic rickettsiae	Endemic rickettsiae
13	0	0	480	0	500
27	60	240	960	0	500
64	60	120	480	0	200

In a case of tonsillitis with an irregular rash, in which diphtheria occurred as a complication on the 16th day the titres with OX19 and OX2 were — 6th day 1-30 14th day 1-120 and 23rd day 1-240. In a case of dysentery with indefinite exudate the OX19 titre was 0 on the 3rd day and 1-120 on the 8th day.

Attacks of murine typhus occurred in two persons who had been inoculated against typhus six and eight weeks previously in both, the Weil-Felix reaction developed in the usual way. So also in five inoculated persons who suffered from fevers other than typhus the agglutination responses did not differ from those occurring among uninoculated persons in otherwise similar conditions.

The author suggests that the non specific reactions may have been due to previous inoculation with T.A.B. vaccine and tetanus toxoid, which had been received by all the patients in the series and which appear to have had some effect in activating the patient's shadow factories for manufacturing agglutinins. The great majority of the patients were British and none of the others had come from places where typhus fever was endemic.

John W. D. McGraw

ANDREWS C. H., KING H. & WALKER, J. Chemotherapeutic Action of Dyes in Typhus Infection of Mice. *Brit J Pharmacol* 1946 Mar., v 1 No. 1 15-20

This important paper is published in the first number of the *British Journal of Pharmacology and Chemotherapy* which makes a welcome though belated, appearance. Some points of general interest are as follows — Among the substances already found therapeutically active in typhus infection of mice are methylene blue, toluidine blue and other dyes of the thiazine group. The authors with VAN DEN ENDE, had already carried out routine tests of methylene blue and toluidine blue on infected mice but had failed to find any benefit, presumably, because the drugs were badly tolerated when administered by the peritoneal route employed in the experiments. These and some other dyes have now been tested on mice infected by the nasal route according to the technique already described by the authors [this *Bulletin* 1945 v 42 20]. Various doses of methylene blue and toluidine blue were administered to the mice (1) mixed with their food (2) by the oesophageal route using measured doses and (3) subcutaneously. Both dyes in suitable doses completely suppressed the development of lung lesions when administered by any of these methods. A murine strain of rickettsia was used, but in two tests of toluidine blue epidemic rickettsiae were employed, and the results were rather less satisfactory.

A large number of dyes were tested for *in vitro* activity by mixing suspensions of murine rickettsiae with solutions of the dyes keeping the mixtures at room temperature for 45 minutes and then injecting them intradermally into the shaved skin of rabbits. It was found that methylene blue toluidine blue six other dyes of the thiazine group and selenium methylene blue in dilutions of 1-500 000 prevented the development of the Giroud reaction. Various acridine dyes including proflavine acriflavine and atebrin were ineffective in strengths of 1-2,000. The results of this test do not always agree with those obtained with the mouse test for example the drugs V 147 and "V 188" which had already been found by the authors to be more effective than methylene blue or toluidine blue in the treatment of mice showed no activity when subjected to the rabbit intradermal test.

PETERSON had already shown that toluidine blue inactivated murine rickettsiae *in vitro* and also had a therapeutic action when administered to infected mice with their food [this *Bulletin* 1944 v 41 935].

Mention is made of the successful treatment of typhus-infected mice with methylene blue by KIKUTH and SCHILLING [*Zent f Bak* 1 Abt. Orig. 1944 v 151 293].

SACHS A Typhus Fever in Iran and Iraq, 1942-43. A Report on 2,859 Cases.
J Roy Army Med Corps 1946 Jan. & Mar v 86 Nos 1 & 3 1-11
87-108 14 figs on 3 pls. 2 graphs & 7 charts. [17 refs.]

[This report will supply valuable material for the typhus-fever chapter of the medical history of the recent war. In the present abstract it is possible to deal with only a few of the interesting observations recorded by the author.]

The disease among British and Indian troops in the area during 1942-43 conformed closely in most respects to the pattern seen in the Mesopotamia campaign during 1917-18 even the case-fatality rate (21.9 per cent.) was much the same as in the previous war when it was 22.75 per cent.

Considering the degree of exposure to infection the incidence among the troops was low—0.78 per mille during the first seven months of 1943. Disinfection with the powder A.L. 63, containing derris and naphthalene was regarded as giving satisfactory results. A Cox type vaccine was available for about one fourth of the troops including some exposed to special risk. Among the vaccinated subjects the incidence was 0.37 per mille among the unprotected it was 0.91 per mille. Only two deaths occurred among the 51 000 protected against 33 among 155 000 unprotected. No attacks occurred later than six weeks after the third dose of vaccine had been given.

Sulphapyridine was given to 336 patients but even when the administration was started before the fifth day there was no reduction in the incidence of bronchopneumonia or in the fatality rate.

The clinical features of the disease were similar to those usually noted in outbreaks of a corresponding kind but a curious observation was that in 55 per cent. of the fatal cases in North Iran death was attributed to circulatory failure or pulmonary oedema whereas in South Iraq these conditions were not reported as having occurred in any case. In one group of 60 cases acute abdominal symptoms occurred in three patients one of whom recovered after an exploratory operation the other two died one of them two weeks after an operation for appendicitis and the other without surgical intervention. In these two fatal cases haemorrhages into the wall of the caecum and massive sub-pericardial haemorrhage were found after death.

The morbid histology of the disease was closely studied, and the characteristic vascular lesions were found but in addition to the usual typhus nodules associated with the small vessels of the brain there were also nodules in the

brain which had no apparent connexion with the vascular system. The detailed description of the microscopic changes is illustrated by 14 good photomicrographs and in three of these rickettsiae are shown. For the demonstration of rickettsiae a slight modification of Wolbach's technique was employed — after fixation of the tissues for 24 hours in Zenker's fluid, paraffin sections were cut and treated with xylol ether and various dilutions of alcohol. The sections were stained for 12–18 hours in a mixture consisting of — distilled water 100 cc. 0.5 per cent. sodium bicarbonate solution 2–4 drops methyl alcohol 3 cc. and Giemsa's stain 2.5 cc. Differentiation was by acetone.

A Weil-Felix titre with *Proteus* O19 rising rapidly to 1–100 or more was regarded as suggestive. The percentage of sera in which titres of 1–1 000 or over were reached in the second week was about 30 among British and Indian troops but only about 9 among Iranian civilian patients. In the fourth week the figures were even more strikingly different 50 per cent. and 8 per cent. respectively. On the other hand, titres of 1–100 or over were reached by the 5th to the 7th day in 50 per cent. of the civilian patients and in only 24 per cent. of the military cases.

Proteus O12 was agglutinated at titres equal to or higher than those obtained with O19 in 10 per cent. of the sera from Iranian patients examined.

In a series of 81 sera of typhus patients from the area, VAN ROOYEN found that the rickettsia-agglutination reaction was of the epidemic type in 75 and of the murine type in 6.

A "Precipitin Colloid Test (Platinum Chloride)" devised by Major L. E. ELKERTOV I.M.S. was tried. The antigen used was a mixture of four volumes of supernatant fluid taken from a rickettsia vaccine after standing for "some time" and three volumes of a 0.684 per cent. solution of platinum chloride. To 18 drops of distilled water (pH 6.6) one drop of serum is added after shaking one drop of antigen is added the mixture is shaken and 18 more drops of distilled water are added. Readings of the turbidity are then made. Positive reactions are said to occur earlier than with the Weil-Felix test, and are regarded as indicating the presence of antibodies of the specific infecting agent rather than the *Proteus* agglutinins.

Numerous guinea-pigs were inoculated intraperitoneally with the blood of patients. With the usual suspensions of macerated blood clot, typhus was transmitted from 8 of 31 cases but better results were obtained by centrifuging 20 ml. of blood mixed with 4 ml. of sterile citrate solution and using 2 ml. of the leucocyte and upper red-cell layer thus obtained as the inoculum. With this method five positive results were obtained in ten cases. Blood drawn in the first week gave the best results samples taken in the second week were slightly less suitable and third-week samples were seldom positive.

The febrile reaction in guinea-pigs was better shown when the intra-abdominal temperature was taken instead of the rectal temperature.

The morbid anatomy of the infected guinea-pigs is described in detail. VAN ROOYEN who examined 31 of the infected guinea-pigs found that the Iran-Iraq strains of epidemic typhus rickettsiae differed from the Egyptian in being more virulent causing (1) a tunica reaction (though this did not amount to a true scrotal reaction) (2) petechial haemorrhages into the peritoneum and (3) in many cases nodule formation in the brain such as was never seen among 200 guinea-pigs infected with the Egyptian strains. *John W. D. Megees*

VIOLLE, H. & CALAMET L. Sur une épidémie de typhus survenue à Marseille au camp d'hospitalisation des prisonniers allemands. [An Epidemic of Typhus in a Hospital Camp for German Prisoners in Marseilles.] *Bull Acad Mèd* 1946 v 130 Nos. 12, 13 & 14 229–31

LEVADITI J. C. & PANTHIER, R. La microscopie en fluorescence de *Rickettsia prowazekii* [Fluorescence Microscopy of *Rickettsia prowazekii*] *C. R. Soc Biol* 1945 Oct. v 139 Nos 19/20 890-92. [Refs in footnotes.]

Rickettsia prowazekii obtained from the lungs of infected rabbits were examined microscopically by ultra violet illumination. They were found to possess no natural fluorescence and although they could be made visible by staining with electro-positive fluorescent dyes they appeared identical in size and form with the organisms stained by ordinary dyes and examined with white light. Fluorescence microscopy therefore does not reveal any structural details such as have been observed with the electron microscope.

LEÓN A P Reacción de Weil Félix tipo Kahn. [The Kahn-Type of Weil-Felix Reaction] *Rev Inst Salubridad y Enfermedades Trop Mexico* 1945 Sept. v 6 No 3 173-9 English summary

The test described appears to be a rapid modification of the Weil Felix test. The apparatus employed is the same as that used in the Kahn test for syphilis and the procedure is on similar lines except that the antigen consists of a highly concentrated and standardized suspension of *Proteus OX19* and that 0.1 cc. of the serum to be tested is used instead of 0.15 cc.

The reading is made within 10 minutes the tubes are kept in the rack, and neither a lens nor a concave mirror is used.

The degree of agglutination in each of the three tubes is recorded as +, ++, +++ and ++++. When a total of 8-12 crosses is recorded in the three tubes the reaction is regarded as positive when the total is 2-7 crosses it is doubtful and with less than two crosses it is negative.

In a series of 33 tests of typhus sera in which the Weil-Felix titre ranged from 1-160 to 1-10 240 the reaction was positive in 30 it was doubtful in three in each of which the titre was 1-160.

In a group of 18 cases of typhoid fever there were no positive but 11 doubtful reactions in this group the Weil Felix titres ranged from 1-20 to 1-160.

Among 828 sera sent for the diagnosis of syphilis 468 gave doubtful and 11 gave positive responses among the same sera 628 gave Weil Felix titres ranging from 1-20 to 1-160 and two gave titres of 1-320 and 1-640 respectively. The 11 sera that gave positive reactions with the author's test reacted at titres of 1-80 to 1-640 with the Weil Felix test.

LEÓN A. P & CANO Carmen. La reacción de fijación del complemento inversa en el diagnóstico del tifo exantemático [The "Inverse Complement-Fixation Test In the Diagnosis of Typhus Fever"] *Rev Inst Salubridad y Enfermedades Trop Mexico* 1945 Sept., v 6 No 3 167-72 English summary

The authors have confirmed the findings of SMORODINTZEF and DROBYSHEVSKAYA, who showed that the presence of a specific antigen could be demonstrated during the first few days in many cases of typhus fever [this *Bulletin* 1944 v 41 1021].

In the present experiments the complement fixation test was carried out by using known antibodies instead of known antigens. The antibodies were obtained by immunizing rabbits with intravenous injections of *Rickettsia prowazekii* var *mooseri* or of *Proteus OX19*.

All of nine typhus patients whose sera were tested before the 10th day of the illness gave strongly positive reactions. The average titre of two of these tested before the 5th day was 1-3 000 the other seven were tested between the 5th and 10th day and the average titre was 1-900.

Among 13 patients tested after the 10th day only four reacted the average titre was 1-300. In all of four convalescent typhus patients and in 13 typhoid patients the reaction was completely negative.

The reaction, therefore appears to be specially useful in the early stages of typhus attacks while the free antigens are still dominant and the standard complement fixation test based on the presence of antibodies, is still negative in most cases.

D'IGNAZIO C. & CODELEONCINI E. Dermotifo in vaccinati. Nota clinica. [Typhus Exanthematics in Vaccinated Persons. A Clinical Note.] *Boll. Soc. Ital. di Med. e Igiene Trop. (Sex. Eritrea.)* 1945 v 5 No 4 7-21

Evidence is produced to show that the original Weigl-type vaccine and a locally produced vaccine have had a striking effect in lessening the severity of attacks of typhus fever among European patients in Addis Ababa during the years 1938-41.

There were 55 cases of which four were fatal, among vaccinated persons. One of the patients who died was attacked before the end of his course of vaccination, and the other three had not been revaccinated during the previous three years. The case-fatality rate among unvaccinated patients was about 21 per cent.

IMBROSCHI G. Sul valore teorico e pratico delle intradermoreazioni con i polisaccaridi del *Proteus X19* e della *Rickettsia prowazekii* per la diagnosi di dermatifo. [The Theoretical and Practical Value of the Intradermal Reaction with the Polysaccharides of *Proteus X19* and of *Rickettsia prowazekii* in the Diagnosis of Exanthematic Typhus Fever] *Giorn. di Batteriol. e Immunol.* 1945 Oct.-Dec. v 33 Nos 10/12 193-216 [11 refs.] English summary

The author has isolated the polysaccharide of *Proteus X19* by the method of ZIMMER and PARKER and, using CASTAGNEDA's technique he has obtained from this two fractions—the OX and OP factors. Both fractions together and separately were used in carrying out the intradermal tests. Rickettsial polysaccharides were also prepared from the intestines of infected lice by Castagneda's method. All the above substances were used in dilutions of 1-100 000 and 1-640 000. A filtrate of *Proteus* cultures was also employed in dilutions of 1-100 and 1-200.

The responses to intradermal injections of all these preparations were essentially similar—inflammatory reactions in healthy persons and in patients suffering from diseases other than typhus also in persons vaccinated with Weigl's vaccine—negative results in typhus patients from the 5th or 6th day onwards and variable responses in typhus convalescents.

The test is regarded as specific and therefore of diagnostic value. A significant response is said to have been obtained in some cases before the Weil-Felix reaction became positive. False positives were observed in some cases when the *Proteus* filtrate was used—these were regarded as being due to sensitiveness of the patients to non-specific proteins contained in the culture medium.

Details of the methods employed and of the responses obtained in a large number of cases are contained in the paper.

MILLER, E. S. & BEESON, P. B. Murine Typhus Fever. *Medicine* 1946 Feb. v 25 No. 1 1-15. [30 refs.]

This description of murine typhus fever is based on a study of 126 cases seen at Atlanta, Georgia, during the eight years ending 1943. The diagnosis was based

on the observation of a clinical picture consistent with typhus fever together with a positive Weil Felix reaction at a titre of 1-160 or over. Some cases in which the Weil Felix reaction was positive were excluded because of the presence of a *Proteus* infection and there were other cases including three fatal, in which the clinical picture suggested murine typhus but in which the diagnosis could not be confirmed by a positive Weil Felix test.

Contrary to the usual belief the disease was as common among negroes as among white men. The month by month incidence, starting from January was—3 2 0 0 2 3 11 19 32 30 17 7

There was a definite history of association with rats in 54 per cent of the cases but only two patients could recollect having been bitten by fleas so that the authors doubt whether infection is conveyed solely through actual contact with fleas contact with faeces of the insects or with urine of infected rats must be considered as possibilities.

The clinical features are described they correspond to those of louse borne typhus of a mild type. A rash was seen in 90 per cent of the white and in 43 per cent of the negro patients. The percentage distribution of the rash was trunk 98 upper limbs 75 lower limbs 59 palms 14 soles 10 and face 10

The only patient who died was a negro woman aged 60 who had uraemia on admission. There may have been three other fatal cases during the period among patients with unconfirmed diagnosis.

PHILIP C. B. WOODWARD T. E. & SULLIVAN R. R. Tsutsugamushi Disease (Scrub or Mite-borne Typhus) in the Philippine Islands during American Re-Occupation in 1944-45 *Amer J Trop Med* 1946 Mar v 28 No 2 229-42 1 fig [11 refs]

The authors state that it is remarkable that incontrovertible evidence of tsutsugamushi disease in the Philippine Archipelago was not forthcoming until its occupation in troops during the present war. They think it likely that cases described by ASHBURN and CRAIG in 1908 [see this *Bulletin* 1944 v 41 437], and other cases reported by FOSTER in 1912 under the name endemic typhus may have been instances of tsutsugamushi disease.

The present paper deals with the disease as observed during the reoccupation in 1944-45.

Altogether 222 cases of which 10 were fatal have been recorded from the following islands—Mindoro 95 Samar 88 Luzon 28 Negros 7 Leyte 3 and Mindanao 1. An eschar was seen in 40.5 per cent of the patients and a rash in 21.2 per cent. These figures are thought to be under-estimates.

Most of the cases in Luzon were closely investigated in 15 of them samples of sera were tested by the complement fixation test by Dr Ida BENGTSOV [whose name as often happens is wrongly spelled as Bengston]. The reaction was positive in every case the titre ranged between 1-64 and 1-32 768 in 14 cases.

The authors isolated a virulent strain of *Rickettsia orientalis* from a patient in Samar Island this strain was subjected to stringent tests.

The infected localities were usually grass-covered land or neglected and scrub-infested coconut groves. *Trombicula deliensis* (syn. *T. walchi*) was found on rats in all the Islands in which the disease occurred except Leyte Island. *T. akamushi* (syn. *T. fletcheri*) was found in Luzon and Negros. The most important of the mite hosts appeared to be *Rattus mindanensis*.

John W D Megaw

Sera of 68 dogs from the same and other localities were then examined by the complement fixation test—titres of 1-256 or over were observed in 11 animals of which eight belonged to families in which cases of Rocky Mountain spotted fever were said to have occurred. Among 41 of the dogs that lived in localities in which Rocky Mountain fever was not known to occur there was only one positive reaction at a titre of 1-128, and no other at a titre above 1-16. For technical reasons the reaction at 1-128 was not regarded as being significant.

Some of the human patients gave no history of having been bitten by ticks, but were known to have pecked ticks from their dogs.

The authors state that the findings suggest more than a casual association between the dog and human cases but that further studies will be needed to elucidate the rôle of the dog in the epidemiology of the disease. They also point out that the dog has been implicated as the reservoir of the tick-borne boutonneuse fever and that Rocky Mountain fever has been transmitted experimentally to dogs by the bites of infected ticks [this Bulletin 1933, v 30 898].

John W D Mcgregor

YELLOW FEVER.

GARNHAM, P. C. L., HARPER, J. O. & HIGHTON, R. B. The Mosquitoes of the Kaimosi Forest, Kenya Colony with special reference to Yellow Fever. *Bull. Entom. Res.* 1946, Feb. v 36 Pt 4 473-66, 3 text figs. & 6 figs on 2 pls. [21 refs.]

Two cases of yellow fever have occurred in Kenya in recent years, one at Kitale (1942) and the other at Kisumu (1943). To ascertain if Kenya forests are infected or if conditions in them are suitable for the development of the disease, investigations were started in November 1942, and continued until October 1944.

The Kaimosi forest lies north of the equator between Kisumu and Kitale. It is a semitropical rain forest covering some 50 square miles—the locality, vegetation, inhabitants and climate are first described and then a more detailed account is given of the mosquitoes of the area.

Adult mosquitoes were collected at ground level and on a fixed platform 55 ft. up a tree in the depth of the forest—they were also taken on a movable platform at different levels. Animal-baited traps attracted nothing, and collecting in huts yielded only small numbers. Larvae were taken at different heights from rot-holes in trees from axils of plants from bamboo and wooden containers hung in trees from bamboo sections placed on the fixed platform in the tree top and from many other places. The authors propose the term *acrodendrophily* to indicate the preference shown by certain mosquitoes for haunting tree tops.

The routine collections produced 55 species of ten genera, of which the following are some examples. *Culex nebulosus* was found at most levels even as high as 60 ft. The commonest larva in tree holes was that of *Aedes capensis* though adults were rare. *Aedes spicargenteus* was the commonest adult—it bites man readily and prefers light forest—larvae were not found in the routine collecting area but were taken from holes in fallen trees in the northern part of the forest. In the denser untouched forest *Aedes fraseri* larvae were found at all levels adults occurring in ground and tree top catches in the ratio of 3:5. Larvae of *Aedes longipalpis* were usually absent from ground-level collections, they and the adults were commoner in the tree-tops. *Aedes aegypti* a low-level breeder was never taken in huts but was frequently found

a mile or more inside the forest away from human dwellings. *Aedes africanus*, a known vector of yellow fever was commonest from August to November. It was found breeding in the buttress roots of trees and in containers up to 50 ft from the ground. Adults were taken mostly in the tree tops.

It seems that the selection of a breeding place depends more on height, shade shape and size than on the chemical composition of the water in it. Analysis of such waters showed that a breeding place of *Theobaldia fraseri* contained 79 parts of oxidizable matter per 100 000 [in Table VI a confusing misprint shows this mosquito as *A. fraseri*].

From the evidence accumulated during this survey it is concluded that conditions in the Kaimosi forest are adequate for the establishment of yellow fever. Some control measures are suggested.

H S LECSON

DENGUE AND ALLIED FEVERS

WEYRAUCH H M & GASS H Urogenital Complications of Dengue Fever
J Urology 1946 Jan. v 55 No. 1 90-93

Among 141 U.S.A. males who suffered from dengue in the South Pacific area in 1943-44 five had dengue orchitis as a complication or sequela of the disease. In one case the right testis became swollen and painful in the second month of convalescence and atrophy was observed six months after the attack. In the other cases orchitis occurred during the febrile stage. In one case the orchitis was unilateral and there was no atrophy in the other three the condition was bilateral it was followed in one case by bilateral atrophy in another by unilateral atrophy and in the third there was no atrophy.

Five patients including two who had orchitis had bloody seminal emissions for one to four months after defervescence. The source of the haemorrhage could not be ascertained.

FLORIO L, HAMMON W McD LAURENT Angela & STEWART Mabel O
Colorado Tick Fever and Dengue. An Experimental Immunological and
Clinical Comparison. *J Exper Med* 1946 Apr 1 v 83 No 4 295-301
4 figs.

Six neuro-syphilitic patients were inoculated with strains of dengue virus obtained from the Pacific area, and in each case a typical attack of the disease was produced. Two of the patients were later re-inoculated with the virus and both were found to be immune. The other four were inoculated 40-80 days later with a strain of virus of Colorado tick fever which had been serially passaged six times through hamsters and then through two human volunteers. Typical attacks of Colorado tick fever were produced in three of the patients; the fourth had no definite reaction but he was known to have spent several years in areas where the disease is endemic.

Another patient was inoculated first with the virus of Colorado tick fever and 69 days later with the virus of dengue. Typical attacks of each disease resulted.

It appeared therefore that there was no cross immunity between the two diseases in spite of their striking clinical and haematological similarity and the approximate equality in the particle-size of their causative viruses.

The other chief difference between the diseases are stated to be the absence of rash in Colorado tick fever, the non-transmissibility of dengue through hamsters and the natural transmission of the diseases by different vectors.

[Colorado tick fever appears to be primarily a disease of lower animals, transmitted from them to man by a tick if, as seems possible, it should come to be regarded as belonging to the same disease group as dengue it would be classed as a tick-borne, zootic, member of the group]

The charts illustrating the paper show that there is a remarkable resemblance between the fever curves and haematological findings of dengue and Colorado tick fever. The average duration of the latter fever is slightly longer the rise and fall of the temperature are somewhat less abrupt and no macular or maculo-papular rash occurs. A diffuse erythema was observed in all the dengue patients, but in two only of the four tick fever patients.

References to earlier work on Colorado tick fever will be found in this *Bulletin* 1941 v 38 694 and 1945 v 42, 117 and 118.]

John W. D. Meyer

POLLARD M. LIVESAY H. R. WILSON D. J. & WOODLAND J. C. Experimental Studies with Bull's Fever *Amer J Trop Med* 1946 Mar v 26 No. 2 175-87 7 charts. [11 refs.]

Two of the authors, LIVESAY and POLLARD have already produced evidence which they regarded as pointing to the probability that the disease was caused by a rickettsia [see this *Bulletin* 1944 v 41 209] and soon afterwards AMIGSTED and BADER reported the isolation of an organism which they believed to be a rickettsia [*Ibid* 666]

After the investigation described in the present paper the authors conclude that "it would be premature to make any definitive classification of the agent without additional studies and that the agent "appears to approximate in size the elementary body agents such as ornithosis more than it does the typical rickettsiae.

In four cases, the infection was transmitted to human volunteers by subcutaneous injection of serum or blood of infected persons. In one of these cases the serum of a naturally-infected patient was used after passage through a Seitz E.K. filter pad but the pad was not afterwards tested for accuracy. Serum from this experimentally-infected volunteer was found infective to another volunteer after passage through a Seitz E.K. pad which apparently was tested and found accurate. In the other two cases whole blood of naturally infected patients was employed.

After two preliminary passages through white mice a strain was passed serially through the yolk sacs of 5 or 6-day-old chick embryos, and small cocco-bacillary bodies were found in smears of the sacs, but not inside the cells. [In the previous report of Livesay and Pollard similar bodies were described as occurring inside the cells in peritoneal scrapings from infected guinea pigs, and in biopsy smears from lymph nodes of patients.] With yolk sac material of the 6th to the 20th passage, four volunteers were successfully inoculated.

Three experimentally-infected volunteers were later challenged with blood of patients suffering from Colorado tick fever and all responded with typical attacks so also did a person convalescent from naturally-acquired Bull's fever when challenged with a hamster strain of Colorado tick fever. It was concluded that there was no immunological relationship between the two diseases.

A strain of infection was obtained from a pooled suspension of the bodies of 337 *Amblyomma americanum* ticks collected from a deer in the area. This strain, after passage through mice and embryo chicks infected two volunteers who were later found immune to a strain of human origin.

The febrile responses in the experimental cases in human beings were usually slight in four of the temperature charts two or three fleeting rises to about

99°F are shown. In all the cases there were relative leucopenia headache body aches and lymphadenopathy

[The authors refer to the reviewer's suggestion that Bull's fever might be related to Colorado tick fever (see this *Bulletin* 1944 v 41 34 and 1945 v 42, 375) and although the present observations go to show that there is no immunological relationship between the two diseases they tend to support the speculative view that both fevers may be caused by filter passing viruses related to the virus of dengue. Final judgment on the exact nature of the infecting agent of this elusive disease must be suspended.] •

John W D Megaw

LAIGRET J & CORCOS A. Observation à Tunis d'une maladie épidémique se manifestant par de la fièvre et des vomissements de sang. [Observations on an Epidemic Febrile Disease with Haematemesis, in Tunis.] *Bull Acad Med* 1946 v 130 Nos 3 4 & 5 55-7

Between mid September and Mid November 1945 the authors saw eight cases of a short, acute fever lasting three to five days and ending with haematemesis. Other cases have been seen by their fellow practitioners in Tunis.

The onset and early stages of the illness conformed to the clinical pattern often seen in dengue and sandfly fever except that a feeling of painful heaviness in the epigastric region and nausea were the most prominent symptoms. About the third day the patients suddenly vomited considerable quantities—up to 300 cc.—of red or black blood. Immediate relief followed and the temperature began to fall, reaching normal within about two days. There were two deaths one in the case of a child aged two years. Although *Aedes aegypti* were abundant it was possible to exclude yellow fever because of the immediate relief following the haematemesis. Bacteriological investigations yielded negative results. The disease was regarded as a severe form of the pseudo dengue which had been prevalent in Tunis since the spring of the same year. There had been hundreds of cases of this fever which differed from dengue in the complete absence of a rash. Sandfly fever also was ruled out because neither relapses nor recurrences of the fever were observed. It was concluded that the fever was like dengue or three-days fever but was neither the one nor the other and that a suitable name would be Tunisian gastroenteric fever.

[The line of reasoning of the authors is not easy to follow. They regard the fever as a severe form of pseudo-dengue yet they suggest a name that is obviously unsuitable for a disease of that type. Their only stated reason for excluding sandfly fever—the absence of relapses—is surprising. Altogether the evidence supplied seems compatible with the view that haematemesis may have occurred as an exceptional complication in eight out of several hundred cases of a fever of the dengue group.]

John W D Megaw

PLAGUE.

BULL. U.S. ARMY MED. DEPT. 1945 Apr No 87 13-16 Plague in Dakar

An outbreak of 567 cases of plague occurred in Dakar "the largest city in French West Africa" in 1944 during the period April to November with a 91 per cent. mortality. No cases of plague had been recorded there since 1837 and so this was essentially a war time epidemic. Most of the interest of this account centres upon the dusting technique and control of the native population. All the actual cases of plague were in native blacks except one in a Syrian and

three in French Europeans." American help was enlisted for the anti-plague dusting programme although this was vigorously entered on only after "the seasonal decline of the plague incidence had begun." A division of the native section of the town was made into zones controllable by a cordon of 200 to 300 gendarmes. Each zone was selected the night before operational treatment to prevent exodus and four or five "outlet stations" were established. Dusting was commenced at about 6 a.m. and was carried out by three or four native workers using 10 per cent. DDT dust with Hudson plunger type dusters. The treatment began at the ankles dusting under the various layers of clothing then dusting at the waist—front and rear then at the sleeves and neck and finally the hair. The clothing was held out and down to form an envelope for the dust which could be seen through the fabric as it was applied on the inside. The operation, to allow of release of the outgoing working native population was complete in about an hour and then the cordon arrangements were modified to deal with the remaining population. It is reckoned that less than 5 per cent. of the people were not dusted. Further anti-flea measures consisted in treatment of the houses "by dusting with 10 per cent. dust and by spraying with 5 per cent. solution in kerosene" where attention was specially directed to the floor and lower walls and beds which were heavily infested with bed bugs as well as fleas. "All public houses such as cafes restaurants bars, brothels cinemas etc. were sprayed with 5 per cent. DDT solution." A survey showed that of 316 houses infested before spraying all but 7 were completely free of fleas two weeks after treatment. The rat population in this area was very large and comprised, more or less equally the Norwegian, Alexandrian and the common rat. The Camtchevill rat was not so numerous. Poisoning of the rats was barred because of danger to children and domestic animals. French opinion was that the best results in plague treatment was obtained by combined sulphadiazine bacteriophage therapy

W F Harvey

KARTMAN L. A Note on the Problem of Plague in Dakar Senegal, French West Africa. *J Parasitology* 1948 Feb. v 32 No. 1 30-35 2 figs. ✓

Dakar experienced an epidemic of plague in 1944 and is regarded as an endemic focus. The present communication insists on the possibility of a human flea being a main plague vector in some regions—in Dakar for example, where the rat flea *X. cheopis* although the commonest species on rats is quite negligible in native huts of the villages about Dakar. Identification of the various species of fleas collected was carried out at the British Museum and showed that the house and body flea in the Dakar area was *Synosternus pallidus*. The genus *Synosternus* is closely related to *Xenopsylla* and the species *S. pallidus* is parasitic on rodents the hedgehog and various carnivora. A very instructive table gives percentages of various fleas collected for examination —

Species	From rodents	From floors
	Per cent.	Per cent.
<i>Xenopsylla cheopis</i>	75.95	1.10
<i>Echinophaga gallinacea</i>	12.83	18.40
<i>Cimexophthalmus felis</i>	4.45	0.35
<i>Synosternus pallidus</i>	6.75	80.15

This shows the complete reversal of percentages for *X. cheopis* and *S. pallidus* according as the collection was made from rodent or from the floors of native huts. "It is suggested that further study of *S. pallidus* as a potential vector of plague in the Dakar area is indicated."

W F Harvey

LAHNUM W. H. Mammals and Plague Distribution in the United States. *U.S. Army Med Bull* 1946 May v 46 No 5 782-5

This contains a useful list of mammals that have been found to be infected or to possess ectoparasites infected with plague

HORNIBROOK J W Streptomycin in Experimental Plague *Pub Health Rep* Wash. 1946 Apr 12 v 61 No 15 535-8

Reports are now appearing which deal with the therapeutic possibilities of streptomycin—from *Actinomycetes griseus*—in human diseases especially those due to Gram negative bacteria. Its toxicity for animals is low and it is more active than streptothrycin. This condensed article which is full of detail gives an account of experiments on plague in mice

The material used contained approximately 200 000 units per gramme killed a 14-gm. mouse on intraperitoneal injection of 20 mgm as 5 per cent solution and failed to kill a 15-gm mouse receiving 10 mgm. In the therapeutic tests treatment was started 3 and 2 days respectively following inoculation with live organisms. If visible swelling at the site of inoculation did not occur the mouse was regarded as non infected and, together with those that died, was excluded from the testing trials. At the end of 14 days from the time of inoculation all surviving animals were killed, autopsied, and the spleens cultured and those mice dying within the 14 days after inoculation of a dose of living plague up to 6 000 organisms in the group were considered to have died of plague. A control series one with no treatment and one with sulphadiazine in the same dosage as streptomycin except for the first dose which was 5 mg rather than 2 mg was set up and this series (Table 5) is summarized. The summary of the entire experiments is as follows—

Streptomycin is thermostable. It is inhibitory to *P. pestis* in broth in a dilution of approximately 1/160 000. When 2 mg (400 units) were given before and 2 mg 24 hours after challenge 10 mice survived for 14 days a dose of plague organisms which killed 70 percent. of the controls. When treatment (2 mg per day) was started 2 days following inoculation and continued for 6 days 9 of 10 mice survived for 14 days. When sulfadiazine was used under the same circumstances 4 of 11 survived 8 of 9 controls died. (Table 5)

W F Harvey

CHOLERA

MARKOWITZ J Experiences with Cholera in a Jungle Camp in Thailand. *J Roy Army Med Corps* 1946 Apr v 86 No 4 150-53 2 figs

[This is one of a remarkable series of articles written in this number by two prisoners of war in Japanese hands. Undoubtedly the entire series should be given wide publicity for their pictorial and textual illustration of sheer devilish, human cruelty and incidentally as testimony to the self-sacrifice and medical ability of the Royal Army Medical Corps under what may euphemistically be described as adverse conditions. The tales far exceed in their general interest the information relating to particular diseases.]

Much the same type of restricted epidemic, if not identical has been summarized below. This epidemic relates to a community of 7 000 more or less disabled British and Dutch prisoners of war. A final table is a Diary of Events and shows that of 134 cases admitted as true cholera 53 were fatal. One concluding remark may be transcribed—Anuria resulting in uraemia was an uncommon cause of death. In brief a patient could die from cholera either from loss of fluid so that his plasma oozed out through the bowels—a

condition comparable to high intestinal obstruction or to shock displayed in a patient grossly scalded by steam or he could die of toxæmia as in any other infectious disease. The actual conclusion to the article stresses certain special points in treatment—distilled water if taken fresh from the still is not pyrogenic and can safely be used. Some advantage is claimed for intravenous infusion with 2 per cent. salt solution over 0.85 per cent. (normal) salt solution. "One litre of distilled water hot off the still is treated with 50 c.c.s of 25 p.c. sodium chloride stock solution. The latter need not be fresh.

W F Harvey

DE WARDENER H. E. Cholera Epidemic among Prisoners of War in Siam. *Lancet* 1946 May 4 637-40 1 chart.

The account of this cholera epidemic presents the reader with another shocking tale of Japanese barbarism and cruelty to defenceless prisoners of war. It brings into prominence the notorious instance of the construction of the Siam-Burma railway. Some very interesting facts emerge from the details given of what was to a very large extent an untreated epidemic under the worst possible sanitary conditions. It lasted apparently in acute form for about 5 weeks and seems to have subsided spontaneously. Total figures of cases at risk were 200 British officers and 1 400 British other ranks. 173 cholera cases were admitted and the deaths among these admissions to so-called hospital numbered 100 (57.8 per cent.). A Dutch camp of 250 sick persons afforded a control series. In this there was only one case of cholera (with recovery) at the same time and under more or less similar conditions to the British. The immunity of the Dutch was not confined to this area but was observed in all the camps on the river. As an explanation of what was a very real difference the suggestion is made that recent vaccination (4 weeks previously) and regularly yearly inoculations protected the Dutch and gave them immunity.

Common complications and sequelae are listed as (1) coma (2) gangrene (3) multiple abscesses (4) severe anorexia leading to quick onset of deficiency disease and (5) residual diarrhoea. These same complications however seem themselves to have been to some extent complicated by the originally sick state of the population at risk, with chronic malaria dysentery beriberi, hyporiboflavinosis and pellagra. As is common in such epidemics the first cases were not recognized. Facilities for treatment were totally lacking and the difficulty was increased by the onset of the monsoon.

BLASS Judith. Etude de la consommation du glucose par les vibrions cholériques non proliférants [The Consumption of Glucose by "Non-Proliferating" Cholera Vibrios.] *Ann. Inst. Pasteur* 1946 Mar-Apr v 72, Nos. 3/4 230-40 4 figs.

A new method of preparing cholera toxin was devised by BERNARD and GALLUT [this *Bulletin* 1945 v 42, 34 807] and the present work is designed to study in detail the utilization of glucose in the process. Experimental work is straightforward to determine (1) the maximum quantity of glucose consumed by a fixed concentration of vibrios where the variable is the glucose content of the medium (2) the consumption of glucose per unit of time with fixed glucose concentration (5/1 000) (3) the consumption of glucose as a function of the medium (4) the products of fermentation of glucose by the non-proliferating vibrios in Ramon bouillon. Products of fermentation were lactic acid, succinic acid, formic acid ethyl alcohol and traces of aldehydes which are the same as those of vibrios grown in synthetic glucose media. The maximum

quantity of glucose utilized was 4 to 5 gm per litre whatever the concentration of the vibrios and consumption was accompanied by a fall of pH from 8 to 5.8 which was fatal to the vibrios. Increase of concentration of the vibrios produces a more rapid fall in the pH. An important factor which determines the utilization of the glucose is the buffering power of the medium.

AMOEBIASIS AND INTESTINAL PROTOZOAL INFECTIONS

LAMY L. Action du para-aminophénylsulfamide (1162 F) sur le départ des cultures d'entamoebadysenteriae (Deuxième note) [The Action of Sulphanilamide on the Starting of Cultures of *Entamoeba histolytica*] *Ann Inst Pasteur* 1946 Mar-Apr v 72, Nos 3/4 295-7

In a previous paper (this *Bulletin* 1946 v 43 442) the author showed that the presence of sulphanilamide [1162F] was favourable to the development of *Entamoeba histolytica* in cultures in the present paper he records experiments which show that in concentrations of 1 1 000 1 500 and 1 200 it favours the development of the amoebae from cysts in faeces sown on the medium without any preliminary treatment.

Cultures of active amoebae were obtained by the 4th day in all three concentrations of sulphanilamide but the amoebae were much fewer in that of 1 200 than in that of 1 1 000. The first subculture made after 7 days was positive and the original culture still showed living amoebae after 10 days the medium was the same as that previously used. The addition of rice starch supplied a nutritive factor to the amoebae and also hinders the growth of *Blastocystis* which is further hindered by the sulphanilamide as are also bacteria.

The author also refers to abstracts to this *Bulletin* of papers by CHENY *et al* [1942 v 39 785] and by RODANICHE and KIRSNER [1943 v 40 455]

RELAPSING FEVER AND OTHER SPIROCHAETOSSES

PAVLOVSKY E N [On the Natural Focal Distribution of the Tick Relapsing Fever in the Turkoman Soviet Socialist Republic.] *Med Parasit & Parasitic Dis* Moscow 1945 v 14 No 3 56-9 1 fig [In Russian.]

The author notes that within the territory of the Turkmenistan the vectors of tick borne relapsing fever are represented by three species of *Ornithodoros*. The most important and widely distributed of these is *O papillipes* the second is *O nereensis* a new species described by the author which lives in burrows and under stones but does not occur in human dwellings while the third *O tartakowskyi* was found in the burrows of rodents. These ticks are occasionally found to be spontaneously infected with spirochaetes of gerbils (*Rhombomys*

[August, 1946]

opimus) in the valley of the river Murgab. To distinguish this spirochaete from the causative organism of human relapsing fever in Middle Asia (*Spirochaeta sodanum*) it was named *S. latyachovi*.

In spite of the presence of these three vectors tick-borne relapsing fever occurs in Turkmenistan only in rare sporadic cases whereas it is much more common in Uzbekistan and in Tadzhikistan. This is due to the fact that *O papillipes* is a rare species in Turkmenistan while *O. narvensis* and *O. latyakovskyi* inhabit biotypes with which man does not as a rule come in contact.

The author describes the case of two men who had taken shelter in a cave near Ashkhabad and who developed relapsing fever nine days later after showing typical traces of tick bites on the skin. An examination of the cave revealed ticks *O. papillipes* with a natural infection of spirochaetes. These facts point to the cave as a natural focus of tick-borne fever which is probably primarily a disease of lower animals (zoonosis) upon which the ticks feed.

SOFIEV M S & LEONOVA N A. [New Data on the Reservoirs of the Virus of Tick borne Relapsing Fever in the Uzbek Soviet Socialist Republic.] *Med Parasit & Parasitic Dis. Moscow* 1945 v 14 No 3 60-65 1 fig [In Russian]

This paper is devoted to a study of the reservoir hosts of tick borne relapsing fever in Fergana (Uzbekistan). Previously the following animals have been found in Middle Asia to be naturally infected with spirochaetes of relapsing fever: dogs, rats (*Rattus turkestanicus*), gerbils (*Rhombomys opimus* and *Gerbillus evermanni*), bats (*Rhinolophus ferrumequinum*) and mice (*Alus musculus severinovi*). In Fergana the principal reservoir hosts were found to be mice 6 per cent. of which proved to be naturally infected. The duration of the disease in these rodents is 12-28 days and it is thought that in the course of the summer probably all the mice became infected. In view of their constant migrations it is suspected that mice serve as carriers of infected ticks (*Ornithodoros papillipes*) from house to house thus serving to disseminate relapsing fever. Experiments with infections with spirochaetes obtained from mice proved that they were able to infect mice.

As regards per cent. of biological infection of ticks (of which up to 17 per cent. are infected) the human strains in various regions and have a distinct vector regarded as an independent

TROITSKY N V [Transmission of the Tick borne Spirochaetosis by the various Stages of *Ornithodoros papillipes*] *Med Parasit & Parasitic Dis* Moscow 1945 v 14 No 3 70-75 [In Russian.]

In the course of its metamorphosis the chief vector of tick borne relapsing fever in Middle Asia, *Ornithodoros papillipes* passes through one larval and from three to five nymphal stages. In each stage the ticks feed at least once on some vertebrate animal. From 20 to 50 or more days after feeding the tick moults and is transformed into the next stage of development. After moulting nymphs of the last stage become adult males or females which feed repeatedly but do not moult.

The author records the results of experiments carried out to determine the ability of different stages of the tick to transmit spirochaetosis. The ticks used in these experiments were collected from a disused and dilapidated piggery and repeated examination of random samples failed to reveal any natural infection among them. Guinea pigs were used both as the source of infection of ticks and to test the infection in the latter.

It was demonstrated that all the stages of development of *O. papillipes* from larva to sexually mature imago were capable of acquiring an infection by ingesting blood containing spirochaetes. They were all capable of retaining the spirochaetes in the successive stages of their development and of infecting susceptible animals by bite. Moreover it was shown that the spirochaetes can be transmitted hereditarily through the ova of the ticks which is an important epidemiological factor. After having fed on blood containing spirochaetes the ticks are capable of transmitting the infection by bite only after the expiration of a certain interval of time which varies with the stage of development. In sexually mature adults it is from one to two months while in larvae and nymphs the interval is determined by the time of ecdysis. Several days after the infective feed the number of spirochaetes in the body of the tick gradually diminishes until it becomes very small thenceforth remaining at a low level.

TROITSKY N V [Experiments on the Application of Carbon Disulphide, Chloropterine, K-Soap and other Insecticides for destroying and repelling the Ticks *Ornithodoros papillipes*] *Med Parasit & Parasitic Dis* Moscow 1945 v 14 No 3 75-8 [In Russian.]

The author notes the importance of *Ornithodoros papillipes* as a vector of tick borne relapsing fever in Middle Asia, where up to 100 per cent. of the population in endemic areas are affected. The existing methods of destruction of the tick are unsatisfactory mainly owing to the inaccessibility of its habitats (cracks in the walls of houses, fine sand or dust in caves, etc.) and also because of the absorption of the insecticides by the substratum. In the present paper an account is given of the results of tests on the effect upon these ticks of various chemicals which were tested both for their lethal and repellent properties.

For lethal tests the ticks were placed in jars or in desiccators with a layer of sand or soil, into which they burrowed themselves. In the case of chloro-pyrrin about 100 cc. per cubic metre acting for five to six hours were required to kill the ticks. Paradichlorobenzene in a dosage of 250 cc. per cubic metre killed all the ticks only after 30 to 38 hours. The best results were obtained

with carbon disulphide which killed the ticks in a dosage of 250 cc. per cubic metre after exposure for 24 hours. It is concluded that the most practicable method for tick infested buildings is the successive treatment with two insecticides. First with carbon disulphide the fumes of which rapidly fill the room and can be eliminated after six to twelve hours and second with paradichlorobenzene which, when placed in suitable positions, prevents fresh infestation of the building.

As regards repellents, the following were tested — Paradichlorobenzene, "C.I." (naphthalene 94 parts, creosote and Iodoform, 3 parts each, which were made into a 5 to 10 per cent. solution in petrol) menthol, soap "K" and tar preparations. These were tested on guineapigs which were either powdered with the preparation or clothed in an overall soaked in a solution of the preparation. None of these tests gave completely satisfactory results.

LEONOVA, N. A. [On the Possibility of Transmission by Lice of the Spirochaetes of Tick-borne Relapsing Fever *Sp. arzbekistanica* (= *Sp. sogdianum*) *Med. Parasit. & Parasitic Dis.* Moscow 1945 v 14 No 3 79-82. [In Russian.]

The author describes the results of experiments designed to test the viability of spirochaetes of the Middle Asia type of tick-borne relapsing fever in the body-lice, and the possibility of their transmission by this insect.

In two series of experiments, lice collected on human beings and bred in the laboratory respectively were allowed to feed on mental patients infected with *Spirochaeta arzbekistanica* for therapeutic purposes. The results were assessed (1) by emulsifying the lice and injecting the emulsion into guineapigs, and (2) by examining the intestinal contents of the lice under dark-field illumination and in stained smears. In a third series of experiments lice were inoculated by Weigl's method, with citrated blood of a guineapig containing numerous spirochaetes. The lice were subsequently dissected and their intestinal contents were examined macroscopically under dark-field illumination.

In all of these experiments the results were consistently negative. It was demonstrated that the spirochaetes lose their viability several hours after inoculation into lice which are incapable of transmitting the infection to guineapigs.

DESFORCES, C. & CAMPAÑA, Y. Sur *Ornithodoros tholozani* (Laboulbène et Mégnin 1892) et sur les ornithodores de l'Asie centrale et mineure (O. *tholozani* and other Ticks of the same Genus in Central Asia and Asia Minor) *Ann. Parasit. Humains et Comparés* 1946 v 21 Nos 1/2, 74-83 3 figs. [10 refs.]

ZARAFONETIS, C. J., D. INGRAM, H. S. & BERRY, J. F. Well-Felix and Typhus Complement Fixation Tests in Relapsing Fever with special reference to *B. proteus* OX-K Agglutination. *J. Immunology* 1946 Mar v 52, No 3 189-99 1 chart [12 refs.]

Well-Felix and typhus-complement fixation tests were carried out on sera of 50 patients under treatment for louse-borne relapsing fever in a Cairo hospital. The diagnosis was confirmed in every case by finding spirochaetes.

Proteus OXK was agglutinated usually in rising titre in every case. In 9 patients the maximum titre of complete agglutination that was observed was 1-40. In 11 it was 1-80 and in 30 it rose to 1-160 or over. Titres ranging from 1-640 to 1-2,560 were observed in as many as 14 of the patients.

Among 351 patients suffering from typhus, typhoid fever, smallpox, and

other diseases the positive reactions with OAK were —27 at 1-40 7 at 1-80 and 4 at 1-160

Among the relapsing fever patients there were two who reacted at high titres with the OY19-agglutination and the typhus-complement fixation tests and who presumably had typhus fever as well as relapsing fever apart from these only one relapsing fever patient reacted with either of these tests at a titre higher than 1-80 and in his case the typhus-complement fixation reaction remained constant at 1-160 on the 2nd 9th and 15th days

The author mentions the findings of ELSDON DEW who observed OAK titres of 1-100 or over in 211 of 650 patients suffering from louse-borne relapsing fever in Ethiopia [this *Bulletin* 1944 v 41 486]

From the table it appears that the maximum OAK titre in the authors relapsing fever patients was usually reached by the end of the second week, though in a few cases the titre continued to rise during the third week

MARTÍNEZ BÁEZ M. & VILLASANA A. Sobre la histopatología de la fiebre recurrente experimental. [The Histopathology of Experimental Relapsing Fever] *Rev Inst Salubridad y Enfermedades Trop Mexico* 1945 Sept. v 6 No 3 185-94 10 figs [14 refs.] English summary (2 lines)

The brains of 15 white rats infected by subcutaneous injection of *Spirochaeta noryi* were examined microscopically 8 were killed during the febrile attack and the other 7 at various times from a day to two months after the end of the attacks when no spirochaetes could be found in the blood.

In rats killed during the febrile attack there was intense congestion of the vessels of the pia mater and of the cerebral capillaries in 3 rats recent haemorrhagic foci 1-2 mm in diameter and of varying depth, were seen in the cortex and at the margins of these haemorrhages spirochaetes were very numerous Spirochaetes were found also in the cerebral capillaries the vessels of the pia mater the choroid plexuses and the parenchyma of the brain. An intense microglial reaction was always present especially in the cerebral and cerebellar cortex, and in the cornu ammonis. No changes were observed in the nerve cells and no reaction in the neuroglia.

In rats killed later no old haemorrhages were seen and it is suggested that they had been absorbed. No special pathological lesions were seen except discrete lymphocytic infiltrations in the pia mater

The paper is illustrated with ten photomicrographs

MUWAZI E. M. K. Penicillin in Treatment of Relapsing Fever *East African Med J* 1946 Feb v 23 No 2, 55-64

A record of the treatment of 37 cases of African tick fever (*Spirochaeta duttoni*) at the Mulago Hospital Uganda carried out in order to compare the therapeutic efficiency of penicillin and arsenicals

The patients were divided into three groups. Eleven patients were treated with sodium penicillin in doses ranging from 100 000 Oxford units in 24 hours to 800 000 units in 72 hours Five of them relapsed and one had seven relapses It is also of interest that several patients in this group were not without symptoms such as headaches and limb pains during the intermissions

Eight patients were used as control and treated with a single dose of 0.6-0.9 gm. of neoarsphenamine (N.A.B.) injected intravenously Five of them relapsed and two showed five relapses each.

Eighteen patients were treated with total doses of from 100 000 to 800 000 units of penicillin in 24 to 72 hours combined with single maximum doses (0.75-0.9 gm.) of N.A.B. Seven relapsed and one patient had four relapses.

The author remarks that it is difficult to assess the therapeutic efficacy of penicillin since natural recovery occurs in a high percentage of cases of relapsing fever. Moreover the initial fever is not prolonged and the apyrexial intervals are of very irregular duration which, combined with the difficulty of controlling the patients made it almost impossible to follow up the cases adequately.

The results indicate however that neither penicillin nor N.A.B. either alone or in combination, is effective in preventing relapses in African tick fever. Both of them shorten febrile attacks but neither is an effective remedy which has yet to be discovered.

E Hindle

SCHUHARDT V T & HEMPHILL, Emmarie C. Brain Involvement as a possible Cause of Relapse after Treatment in Spirochetal Relapsing Fever. *Science* 1946 Apr 5 422-3.

A discussion of the results of experiments on the treatment of rats infected with a strain of relapsing fever transmitted by *Ornithodoros turicata* by means of penicillin sodium administered both intraperitoneally and intracranially [see this Bulletin 1945 v 42 735]

A total of 59 rats were infected with similar doses of blood containing spirochaetes and penicillin therapy was begun on the second or third day after their blood became positive. Twenty-five rats were each given 1 000 units of penicillin in a single intracranial injection and the 23 survivors received 1 to 14 intraperitoneal injections of penicillin at 3-hour intervals in doses ranging from 4 400 to 50,900 units per kgm. body weight. Nineteen rats were treated by intraperitoneal injections alone and nine were kept as untreated controls. All these nine were brain positive when tested 31 days later.

The total of 27 treated rats which received less than 40 000 units/kgm. all relapsed, regardless of whether they received intracranial injections or not. The relapse and positive brain infections of the 13 rats receiving intracranial injections are interpreted as the result of inadequate therapy to cure the infection in blood or visceral tissues. Fifteen rats received more than 40 000 units/kgm. and 10 of these intracranial penicillin. Of the latter 6 received only 4 injections and 3 showed positive brain infections possibly as the result of adhering infected blood the other 4 rats remained negative including brain passages, after 31 days.

The 5 rats receiving no intracranial injections all relapsed or showed positive brain infections.

The results support the view that after intraperitoneal treatment, relapses may occur as the result of spirochaetes re-entering the blood after persistence in the central nervous system.

Box, R. Het voorkomen van de rattebeetspijl in de oorspeekselklier van de muis. [The Presence of *Spirillum minus* in the Ear Salivary Glands of Mice.] *Acta Leidensia (Scholas Med Tropicae)* 1940-41 v 15-16 143-51 [12 refs.] English summary

Many weeks after the infection the causative agent of rat-bite fever is found in larger numbers in the ear salivary glands of mice than in their blood. This speaks in favour of a possible rôle of the saliva in the transmission.

"The author has not succeeded in demonstrating the organisms in sections of salivary glands and other organs. So she doubts the exactness of the researches of KURAMA, KOBAYASHI, KARAI and others who might have taken nerves for Spirilla."

NITTI F CONGE M & KAUFFMANN G Mlle Traitement du sodoku expérimental du cobaye par de faibles doses de pénicilline [The Treatment of Experimental Rat-Bite Fever in the Guinea-pig with Small Doses of Penicillin.] *Ann Inst Pasteur* 1946 Mar-Apr v 72 Nos 3/4 294-5

Few guinea-pigs were available and only small quantities of penicillin but four experiments were made with daily doses of 600 to 1 000 units per kgm in each experiment and in every guinea-pig treated, the spirilla disappeared from the blood and in some cases the animals ceased to lose weight. Relapses occurred after 4 to 30 days according to the dosage of penicillin given and the animals died. The authors think that at least a certain proportion of cures may be hoped for with the use of larger doses. [See also LOURIE & COLLIER this *Bulletin* 1944 v 41 293] J F Corson

LEPROSY

CERRI B Ricerche sul sangue e sul midollo sternale nella lebbra. [Studies of the Blood and Sternal Marrow in Leprosy] *Haematologica* Pavia. 1942 v 24 Nos. 3 & 4 167-244 269-334 12 figs (2 coloured) & 6 graphs [47 refs.] French summary

Not all of this long article is taken up with the subject as stated in the title. For example, several pages are given to the history of sternal puncture and its uses in venereal and cutaneous diseases including syphilis and Kaposi's disease which have nothing to do with leprosy. On the other hand, the author includes other matters concerned with leprosy such as the results of biopsy of the skin and of examinations of the nasal mucus.

For his specific purpose the author took blood from the finger tip and marrow from the sternum, both in the morning of the same day and also material from the nasal mucus and from puncture of an inguinal lymphatic gland and, when the patient consented, of biopsy material from a leprotic lesion. For examination the methods of staining were the May-Grünwald-Giemsa and the Ziehl-Neelsen.

The patients comprised 23 with the nodular type of disease 11 with mixed leprosy and one with the nervous form. Details of each of the 35 are given, in letterpress and in tables the examinations were very full. Of the blood estimations were made of the haemoglobin the number of red and white cells and a differential count of 400-500 of the latter. The examinations of the marrow were much more exhaustive 20 varieties of cells were counted and their relative percentages calculated. [We have checked the first ten of these tables and in one instance only does the total come to 100 per cent. all the others exceed this ranging between 102.2 and 110.6 per cent. The percentages in the blood counts are more often correct.] Leucopenia of 2 600 and 4 150 respectively was found in two cases the one in the nodular group the other in the mixed leprosy group. Leucocytosis up to 14,850 per cmm. was found in five 2 of the first group (nodular cases) and 3 of the second (mixed). Another of the first group during a leprosy reaction, had a leucocytosis of 26,900 per cmm. Anaemia was a constant feature, nearly always hypochromic with some degree of anisocytosis and, rarely, poikilocytosis. neutrophil metamyelocytes were also always present but not in large numbers. non-segmented neutrophils were more common up to 35 per cent. of the neutrophils.

In the marrow points specially noted were asynchronism of maturation of cells asymmetry fusion of chromosomes pyknois and staining irregularities. In general the marrow showed abundance of worn-out cells scarcity of areolar tissue and of vacuolated cells activity in production of granuloblasts raised leuco-erythroblast ratio and increased karyokinesis increase of myelocytes and metamyelocytes and predominance of erythropoiesis over leucopoiesis lymphocytes and monocytes showed a moderate increase eosinophiles generally below normal haemocytoblasts and histiocytes variable, but on the low side. In general the marrow presented signs of degeneration of cells and departure from the normal in size relative proportion of nucleus to protoplasm, of "over-granulation" with atypical forms and staining affinities, and atypical also in the number of nuclei in the granulocytes and polychromatophilla with basophilic granulations in the erythrocytes.

In the material obtained by puncture of the inguinal glands the author noted cells of varied size sometimes "very large" (size not stated), with a histioid or monocyte nucleus the protoplasm basophilic with acidophilic particles, with clean-cut edges and vacuolated also typical plasma cells some binucleate and Türk's cells.

Biopsy specimens were obtained from five patients and from four material from scarification of lepromata there was nothing calling for special mention in these.

Examination for bacilli of leprosy in the marrow gland-junction skin and nasal mucus may be summarized as follows They were found in all four situations in six of the patients and all were in the first group of nodular cases In the marrow smears in 16 of the first group three of the second (mixed leprosy) not in the nerve-type patient. The last may be disposed of in a few words the skin was not examined but no bacteria were found in any of the other situations. As regards the gland-puncture results In the 23 of the nodular group Hansen's bacteria were seen in 17 few in some, numerous in others sometimes singly sometimes in masses five were not examined by gland puncture and in one of those examined none was found. In the second group of 11 they were found in five and not found in three three were not examined. The skin was examined in nine of the first group only and infection was present in all. The nasal mucus was negative in three of the first group positive in the other 20 negative in two positive in nine of the second group absent, as already stated, in the nerve case

H Harold Scott

SHLEMOVITZ, N. Leprosy a Report of Nine Cases among Natives of the Mount Hagen Area in New Guinea. *Med. J. Australia*. 1946, Mar 16 v 1 No 11 369-70 4 figs.

This is an illustrated account of leprosy cases found in the mountainous interior of New Guinea at an elevation of 5,000 feet, where the disease had not previously been reported. It is however well known in the low coastal areas in which there was a leprosarium at Mandang. Some of the cases are of long standing and the disease therefore is not of recent importation. Three of the patients showed advanced neural signs with the development of claw hands three more were earlier neural cases with discoloured patches and alterations of sensation. Another showed thickened ulnar nerves without deformity of the hands but with a few ulcers about his ankles. The remaining two were lepromatous cases one showed large nodules containing numerous lepra bacilli, and the other involvement of the nose and larynx. Arrangements for isolation of these patients are being considered, and it is stated that leprosy undoubtedly exists in other localities in the interior of New Guinea.

L. Rogers.

ARNOLD H. L. Jr. Differentiation of Lepromatous from "Neural" Leprosy The Basis, a Method, and Report of Five Cases. *Arch Dermal & Syph* 1945 Nov-Dec. v 52, No 5 354-64 7 figs. [Refs. in footnotes]

This is a useful and up-to-date paper by an experienced worker in Hawaii on the diagnosis of the types of leprosy as a basis for prognosis and preventive measures. The author deprecates the use of the term mixed leprosy in that it is not applied to a mixture of the main lepromatous and neural types but really means that the sites of involvement—both skin and nerves—by the lepromatous forms are mixed for in nearly every case of leprosy lesions of both the skin and the nerves are found. Lepromatous cases are characterized by the presence of raised red patches or diffuse granulomatous infiltration of the skin rich in *Mycobacterium leprae* and in advanced cases many of the internal organs are involved nerve trunks are also implicated with resulting paralyses and loss of sensation of the extremities. The eyes nose and larynx suffer severely in late cases and chronic nephritis and amyloid disease of the organs are important complications. The skin lesions can be differentiated from the tuberculoid variety of neural leprosy only by microscopical examination which shows round and spindle-shaped histiocytes loaded with the causative bacilli and with fat. The nerve trunks show very similar changes. The lepromun test is negative and the sedimentation rate increased. Lepra fever occurs at times with exacerbation of the symptoms and the appearance of new lesions resembling erythema nodosum the prognosis is bad. On the other hand, in neural leprosy small superficial nerves are involved in relation to skin lesions showing tuberculoid changes but containing extremely few scattered, bacilli local discoloration of the skin and changes in sensation are found. The microscopical characters of these lesions are shown in illustrations. Prognosis in neural cases is comparatively good and spontaneous recovery may ensue they seldom require to be isolated. Isolation however is necessary in all lepromatous cases except very early ones. L. Rogers

FITE G. L. & GEMAR F. Regressive Changes in Leprosy under Promin Therapy *Southern Med J* 1946 Apr v 39 No 4 277-82, 1 fig

This important paper records the results of the use of promin in the treatment of leprosy over a period of four years. Daily intravenous doses usually of 5 grammes have been given over periods of three weeks with an interval of one week between the courses. In some cases this treatment was continued for more than 4 years with beneficial results in nearly all. Clinical improvement is slow and reduction in the number of lepra bacilli still slower but progress is nearly always steady and relapses or febrile exacerbations very rare. Repeated microscopical examinations of the skin lesions showed disappearance of inflammatory signs and diminution in the number of bacilli but the latter often did not disappear completely although typical cigar like packets of organisms became extremely rare. The greatest decline in the number of organisms was seen during the fourth year of treatment by the end of which they had disappeared from 21 of 42 patients. With one exception the skin lesions showed extensive evidence of atrophy. The deeper foci of infection showed the greatest diminution in size and in the number of bacilli this may be due to the fact that there is a better blood supply at these sites which brings the drug into closer contact with the bacilli. The lipoids in the affected tissue remain undiminished, and many vacuolated fatty cells persist. Fibrosis is not a feature of regressive lesions.

The drug appears to act by ridding the blood vessels of lepra bacilli and so preventing their spread throughout the body to form new and progressive

lesions. There is little evidence that promin destroys the bacilli in the tissues but they gradually decrease in the old lesions in accordance with the self-healing tendency of leprosy. This explains the slowly beneficial action of the drug. The absence of acute reactions strongly suggests the destruction of the organisms in the blood and the prevention of their dissemination through the body as the essential action of this treatment and their gradual reduction in the tissues to the point of final disappearance as was observed in 10 out of 32 cases treated for four years. A still more powerful bactericidal agent is required for the chemical destruction of bacilli within the tissue cells and especially in the globi laden with the organisms. Chemotherapeutic research with drugs of allied composition seems most likely to furnish this requisite.

DE WILDEMAN E. A propos de médicaments antilépreux d'origine végétale. V Des "Ephedra" et de leur constitution chimique [Drugs of Vegetal Origin used in Leprosy. The Chemical Composition of Derivatives of Ephedra.] *Inst Roy Colonial Belge—Bull. des Séances* 1945 v 18 No 2 398-412. [Refs. in footnotes]

The author first discusses the history of the study of plants of the genus *Ephedra* in different parts of the world—these plants yield ephedrine and closely allied alkaloids which are used chiefly in the treatment of asthma, but have occasionally been tried in leprosy. Thirty-one botanical varieties are enumerated in alphabetical order with brief notes of work on those which have been investigated, and suggestions that have been made for their medicinal use. Drugs of this series have been used in China for many centuries, but varieties are met with in India, North Africa and America. Mention is made that preparations from these plants have been used in leprosy but no evidence is given relating to results obtained regarding which the author states that it is difficult to form any conclusions. This paper has therefore little medical interest.

HELMINTHIASIS

ALVES W. The "Public Health Cure" of Bilharziasis with One-Day Course of Antimony. *South African Med. J.* 1948 Mar 23 v 20 No. 6, 148-7

A modified form of the intensive treatment of bilharziasis devised by the author [this *Bulletin* 1945 v 42, 815] and by ALVES and BLAIR [this *Bulletin* 1946 v 43 344] is described in this paper.

A group of 131 Africans bilharzia-positive by a cercarial antigen skin test was divided into three groups, each of which was treated under a different dosage scheme with sodium antimonyl tartrate by the slow-injection method previously described as follows—

- | | |
|---------|--|
| Group A | 6 grams sodium antimonyl tartrate (S.A.T.) in three doses of 2 grams at four-hourly intervals. |
| Group B | 7½ grams S.A.T. in three doses of 2½ grams at four-hourly intervals. |
| Group C | 8 grams S.A.T. in four doses of 2 grams at three-hourly intervals. |

The treatment thus occupied only one day. No marked reactions occurred, nor was there any obvious difference between the groups receiving different doses.

The S.A.T solution was prepared as follows —

Tap water	2,000 cc
Glucose B.P	100 grammes
Sodium chloride A.R	17 grammes
S.A.T powder B.P	q s. to make either 2 grains or 2½ grains per 10 cc solution

Dissolve filter through paper and autoclave at 120°C. for 20 minutes in 3 000 cc. flasks. Distribute under sterile conditions into sterile vacoliter bottles fitted with two-hole rubber stoppers. Seal stoppers with 6-in squares of previously boiled thin oilskin—similar to jaconet—and tie down. Store in cold room at 4°C

The used vacoliter bottles would not stand autoclaving when filled, but were sterilised without damage in the hot-air oven at 160°C. for one hour. Hence the necessity for autoclaving the solution in flasks and transferring it. The rubber stoppers were boiled with the oilskin squares.

For use the oilskin covering a hole in the rubber stopper was wiped with alcohol and pierced with a syringe needle and the tip of the syringe (minus needle) was inserted when 10 cc could readily be withdrawn. The hole was then covered with sterile cotton wool soaked in alcohol.

Ten cc. of the solution contained either 2 grains or 2½ grains of S.A.T and no further manipulation was necessary.

These solutions were used up to seven weeks after their preparation and storage and there was no evidence of deterioration to toxic material.

The drug cost of treatment was ½d. per patient.

Urines and stools of every patient were examined two weeks and four weeks after treatment. Seven were passing a few dead eggs on the first examination and one on the second examination but in none were living eggs found.

The significance of this treatment lies in the fact that it provides a rapid method of disinfecting an infected population for a time at least which if used in conjunction with snail destruction should prove to be a valuable weapon in anti-bilharzial campaigns.

CAIRO MINISTRY OF PUBLIC HEALTH MEDICAL AFFAIRS Annual Report of the Bilharzia Snail Destruction Section 1943 (BARLOW C. H. (Expert) & ABDEL AZIM, M. (Director) 27 pp 3 maps (2 folding) 2 diagrams & 1 graph. 1946 Cairo Govt. Press

This report consists mainly of an account of the activities of the Snail Destruction Section during 1943 and the first part of 1944.

The methods of snail eradication which are summarized briefly remain essentially the same as those described in the 1942 report [this *Bulletin* 1945 v 42, 1017] and consist of a preliminary survey of canals and drains to note the location and numbers of snails which is followed by treatment of the infested parts by means of (a) clearance of weeds and snails by mechanical methods such as nets, diggers, manual labour and (b) sulphation by means of copper sulphate.

The progress of the campaign in Fayoum Province is reported upon and its success is indicated by a comparison of the 1942 ratio of the number of infested streams to the number surveyed, with the same ratio in 1943. This shows a reduction from 25 per cent to 12 per cent.

The Fayoum campaign was succeeded late in 1942 by a similar one in Giza Province. The topography of this area is described, and for the purposes of

Tropical Diseases Bulletin

survey and treatment the province was divided into 14 areas 11 on the west and 3 on the east of the Nile. In 1943 4 111 streams were surveyed and 1 816 (39 per cent) were found to be infested with snails. In 1944 after treatment the percentage of infested streams fell to 22 per cent. The results of the work are also expressed by an estimation of the snail populations in infested streams before and after treatment. Thus, before treatment 13,688 *Bulinus truncatus* were collected by dipping in infested streams (presumably with the standardized collecting nets described in the previous report). This number represents an average of 83 snails in 100 dpa. After treatment the average fell to 37 snails per 100 dpa. Only two of the 14 areas were infested with *Planorbis bosnyi*. The average number of this species per 100 dpa was 125 before treatment and five after treatment.

Concerning the Dakhla Oasis the field of a series of anti-bilharzial measures between 1928 and 1935 some comments are made upon the results of a mission which revisited this area in 1943.

A summary of the results of research work having a bearing on snail destruction is included in the report and is described under the four headings: (1) Seasonal variations in the snail population of the fresh-water streams of Egypt. (2) Observations on the distribution of *Bulinus* and *Planorbis* snails during the winter closure 1943-1944. (3) Palm leaf traps in main canals and drainage. (4) Random examination of *Bulinus* and *Planorbis* snails for schistosome infection in Giza Province.

A comprehensive map illustrates the scope of a projected 6-year plan for snail eradication along the course of the Nile, from Aswan down to and including the delta.

VERSIANI V MARTINS, A. V & SOBRINHO O P Esquistosomose mansônica no estado de Minas Gerais. I—Município de Belo Horizonte. [Infestation with *Schistosoma mansoni* in the State of Minas Gerais.] *Arquivos do Inst. Químico-Biol. Estado de Minas Gerais* 1945 v 1 71-80 3 figs. [28 refs.] English summary

The existence of *S. mansoni* infestation in Minas Gerais has been known for more than a quarter of a century. The authors have lately examined the faeces of about 1 per cent of the population of 38 municipalities in the State, choosing in particular children of school age 7-15 years. The method utilized was to take about 2 gm of the faeces in a Borel flask emulsify with a little water and rapidly filter through a metal sieve of 80-100 meshes per sq cm. into a conical glass. This was allowed to settle for 20 minutes. Fifty cm. were then withdrawn with a pipette from the bottom of the sediment and examined under low power. Except for better identification of doubtful elements only one examination was made of each sample.

An average of 98 samples was obtained from each of 24 schools, 2,352 altogether. 294 or 12.5 per cent were positive. Of 733 girls 47 (6.4 per cent) of the 1,819 boys 247 (15.23) were positive. 1,234 were from whites and 142 (11.5) were positive among these. 331 were from blacks, 40 (12.08) and of 787 mulattoes 112 (14.23) were positive. Those of the poorest class were most infected and the rate rose steadily with age from 7-94 per cent. at 8 years to 25 per cent. at 15 years, the intermediate rates being 11.02 13.13 18.19 17.42 and 23.45 per cent. Again, the highest infestation rate was in those living in rural zones. Thus, of 381 town-dwellers 33 were positive (8.6 per cent.) of 1,888 living in the suburbs 225 (12.04) of 103 rural 38 (34.9) were positive.

H Harold Scott

OLIVEROS NAVA B Estudio estadístico del Servicio Antibilharziano de El Valle Centro de Educación Sanitaria [Statistical Study of the Anti-Schistosomiasis Service in the El Valle District (Venezuela)] *Rev Sanidad y Asistencia Social* Caracas, 1945 Oct-Dec. v 10 Nos 5/6 667-86 5 graphs

The author has analysed the histories of 1,358 patients suffering from infestation by *Schistosoma mansoni*. The commonest reasons for the patient applying for treatment were headache, dysenteric symptoms and abdominal pain with general malaise. The chief symptoms were malaise and headache in 54-58 per cent and general debility in 53 per cent. Blood and mucus in the stools were seen in only 14 per cent. Enlargement of the liver was present in 58 per cent, of the spleen in 63 per cent, but the latter was palpable in 15 per cent only; the enlargement in the others being by percussion only [enlarged upwards]. More than half the cases (820 or 63 per cent.) occurred in El Valle and 184 (14 per cent.) in El Tuy. Fifty other localities are mentioned but generally few in each; only three had more than 50 and 12 had only two cases.

Treatment has been by tartar emetic, starting with 0.03 gm. The total dosage ranged between 1.2 and 1.8 gm. in 656 cases. 489 required a second course and 73 a third. Other drugs were tried such as Neostan (? Neostam), Repodral and Stibamine (? Stibamine glucoside) but the numbers of patients to whom these were given are not stated nor is there any mention of dosage. All that is said of them is that Repodral has the advantage of being given intramuscularly and Stibamine orally. Neostan is not referred to again.

MAGATH T B & MATHIESON D R. Important Factors in the Epidemiology of Schistosomiasis in Leyte. *Amer J Hyg* 1946, Mar v 43 No 2 152-63 5 figs.

The authors attempted to evaluate the factors responsible for the spotty distribution of schistosomiasis in Leyte. They give an account of the ecology of the snail intermediary *Schistosomophora* (*Oncomelania*) *quadras* whose habitats are confined to certain types of water but have a wider distribution during some months in the year. Typically they inhabit the margins of slowly moving water in small creeks where shade is abundant. They were not found in marshy land periodically flooded with sea water, in large rivers where the flow is rapid and the banks are sharply defined by steep sides without adjacent swamps, in ditches with impermanent water or water exposed to the sun in stagnant water, nor in large slow flowing rivers.

The factors governing the localization of the disease were critically examined in Palo, a village of high endemicity. [The value of the detailed description of the topography of this place would be greatly enhanced by a sketch map.] The conclusions reached are that snails become infected mainly in the immediate neighbourhood of defaecation sites; that human infections may occur at any season but that there may be a strong seasonal incidence; that the disease in Leyte is not occupational but is essentially one of childhood; that of the reservoir hosts pigs are more important in infecting snails than are dogs and that wild rats are of little importance in this respect.

The determination of the exact type of water in which people may become infected is of great importance. Considerable space is devoted to a discussion of this problem and to the possibility of contracting the infection in large bodies of water. The trend of the authors' argument is against this possibility. [See also this *Bulletin* 1945 v 42 1018, 1946 v 43 350.]

MAGATH T B. & MATHIESON D R Factors affecting the hatching of Ova of *Schistosoma japonicum* J Parasitology 1946 Feb. v 32, No 1 64-8.

The functions of development and hatching in the case of *S. japonicum* eggs are very different, and are closely inter related with the different physical environments which characterize the mammalian body and the exterior. While the eggs can develop at body temperature and in the normal salinity of the body either of these conditions will prevent them from hatching. On leaving the body they are released from the influence of these inhibiting factors and hatch readily at the lower temperature and salinity usually encountered in tropical waters if a third factor a sufficiency of oxygen is also present. The experiments described in this paper were designed to determine the factors which prevent *S. japonicum* eggs from hatching within the tissues or in the faeces of the definitive host.

It was found necessary to dilute the faeces with water until much of the putrescent material had been disposed of to obtain a large hatch of miracidia. Hatching continued for several hours and then fell away when the water became foul. Active hatching was renewed when the water was aerated with a bicycle pump or a stream of oxygen. Observations on temperature effects showed that eggs remained viable but would not hatch up to 9 days at 18°C. The optimum hatching range was 25°C to 31°C. and at higher temperatures it was inhibited. No hatching took place in the presence of sodium chloride concentrations as small as 0.7 per cent.

The miracidia were subjected to a gradually increasing temperature (0.5°C. per minute until 37°C. was reached) and it was noted that their most rapid motion was at 33°C. Thirty minutes exposure to 37°C was usually fatal. Two minutes exposure to a 1.3 per cent. solution of sodium chloride was fatal, but the eggs survived for 1 hour in a 0.66 per cent. concentration and after an hour in a 0.2 per cent. concentration they were apparently normal and might infect the snail intermediate.

FAUST E. C WRIGHT W H McMILLEN D B & HUNTER, G W
The Diagnosis of Schistosomiasis Japonica. I. The Symptoms, Signs and Physical Findings Characteristic of Schistosomiasis Japonica at Different Stages in the Development of the Disease. Amer J Trop Med 1946 Jan. v 26 No 1 87-112 7 figs. (38 refs)

Far Eastern schistosomiasis katayama disease was first recognized in 1847 the clinical picture of the advanced disease was adequately described in 1883 and its causative agent was discovered in 1904 Japanese medical literature after 1883 contains much information on the aetiology epidemiology pathology and attempted prevention of the condition but there is little or no information on its incubation period and onset. In 1923 there was a report on a group of 40 Chinese boys and an adult American who swam in infected water and were all ill some seriously one month later. Other outbreaks with less definite dating of the actual infection have been recorded by European and Chinese workers.

Several hundred cases of Eastern schistosomiasis occurred among American troops within a limited period of the invasion of Leyte Island in the Philippines (October 1944). A group of men in a R.A.A.F. construction squadron were also infected there. These two groups of cases were available to the authors for the study of the late incubation the acute and the early chronic stages of the infection. For the purpose of comparison advanced chronic infections were available in natives in hospitals in Leyte and in Mindanao.

The factors governing the severity of the clinical manifestations of infection in the individual include —(a) the intensity of available cercarial infestation

in the infecting water (b) the gross area of skin and particularly of mucous membrane exposed to attack (c) repetition of exposure to infestation and (d) the reaction of the individual patient to the parasites. At the actual time of infection by the cercariae needling sensations may be felt in the skin. A few days later there is an irritating often unproductive bronchial cough which lasts for several days. Two weeks later moderate or severe urticaria may appear overnight and the patient first appreciates that he is ill. Headache mental dullness tiredness and loss of weight and a feeling of fullness and of pain on pressure over the epigastrium then develop chills and sweats occur at night. These symptoms increase until some four to five weeks after the initial infection when there is a sensation of fullness and pain in the right hypochondrium general abdominal discomfort mucous diarrhoea or a bloody dysentery and marked loss of appetite.

The manifestations appear essentially in this order but not all of them are usually encountered in each patient.

The acute stage of the disease sets in when the mature fertilized female worms begin egg laying and the eggs appear in the stools within a few days. The acute stage lasts three or four months and then continues as the early chronic disease. Four types of the acute stage of Eastern schistosomiasis can be distinguished—(1) the fulminating (2) the severe with sudden onset (3) the insidious and (4) the asymptomatic. In type (1) the fulminating death often occurs before a specific diagnosis is reached and in the one case of this type seen by the authors death occurred in spite of immediate antimony treatment begun before a parasitological diagnosis was made an autopsy showed a massive parasitic infection which had caused an overwhelming intoxication with the metabolites of the worms and their eggs.

In type (2) the severe with sudden onset the appearances 4 to 5 weeks after infection are those of an undiagnosed fever urticaria angioneurotic oedema gastrointestinal distress acute diarrhoea dysentery dengue infectious hepatitis or an upper respiratory infection. Within 81 days of first infection 61 per cent of those found to be infected in one unit had been admitted to hospital severely ill 71 per cent of these infected men had eosinophilia of less than 10 per cent and one patient had 90 per cent eosinophilia. More detailed clinical accounts of these cases are to be published. Two new features relatively common in these severe military cases were nuchal rigidity (soreness and stiffness of the neck) and the development of yellowish nodules on the mucosal surface of the lower sigmoid colon and adjacent part of the rectum. The yellowish nodules were slightly elevated papillae 1-3 mm in diameter which on scraping were found to contain eggs of *S. japonicum*.

In type (3) the insidious infections a gradual development of symptoms and signs took place over a period of one to three months after the usual incubation period. Several such cases were seen in the military groups and difficulty was experienced in diagnosis owing to the mildness of the manifestations. This was even more the case in type (4) asymptomatic infections where the diagnosis was made by routine stool examinations.

The complications of Eastern schistosomiasis encountered were (a) extension of the lesions from the abdominal viscera to other organs and tissues of the body and (b) secondary infections or disease processes. Extension of the lesions by the carriage of eggs to the lungs was seen in one case in other cases eggs were transferred by an unexplained mechanism from the portal circulation to the systemic circulation and lodged in end-arterioles of the toes the skin or the central nervous system. The complicating infections encountered included malaria tuberculosis amoebiasis and other diseases of common occurrence in the tropics all of which may obscure the clinical picture.

Passage into the early chronic form of the disease is due to the continued discharge into the body of metabolic products of the parasites and the toxæmia resultant on their presence. The accumulation of the very large numbers of eggs produced by this species which fail to reach the exterior act as foreign bodies particularly in the intestine the liver and the mesentery with the resultant development of the classical changes associated with the advanced stage of the disease may develop in cases of very heavy infestation but more commonly the onset of this stage is deferred for four or five years. In natives subject to repeated reinfection manifestations of the early and the advanced stages are often coincident. In the military cases no significant chronic lesions were observed up to a year after infection these may be expected in untreated or inadequately treated cases in five to ten years time.

The authors record in considerable detail the progress of Eastern schistosomiasis in the eight surviving members of a Filipino family infected in a newly discovered endemic focus of infection in Mindanao and they go on to describe other indigenous cases in the same locality. Features of the Filipino cases were the absence of the nuchal rigidity so conspicuous in the American military cases the absence of significant eosinophilia at the times of examination and the absence of the severe and prostrating onset which characterized the majority of the American cases admitted to hospital.

[This paper contains much information and should be consulted in the original by those interested. See also this Bulletin 1945 v 42, 1018.]

FAUST E. C. The Diagnosis of *Schistosomiasis Japonica*. II. The Diagnostic Characteristics of the Eggs of the Etiologic Agent *Schistosoma japonicum*. *Amer J Trop Med* 1946 Jan v 29 No 1 113-23 27 figs.

The typical, viable, mature ova of *Schistosoma japonicum* are readily identifiable but occasionally plant cells in faeces are mistaken for atypical eggs. A chain of eggs distends the venule in which they have been deposited by the retreating ovipositing female which while egg-laying is grasped and held in position by the male worm. The newly-laid egg is immature but normally matures rapidly and the larva contained in it secretes an enzyme through the shell which aids in the escape of the ovum from the containing vessel and in its migration through the tissues into the lumen of the gut. Back-pressure to this process. Immature or degenerate eggs as well as mature viable eggs passed in faeces and their recognition may present difficulties. Descriptions with camera-lucida drawings of the immature and maturing and dead eggs of *S. japonicum* and of different types and stages of degenerate and dead eggs of *S. japonicum* voided in the stools of infected dogs and men. Careful search of the stools of infected persons by the skilled laboratory worker will usually be rewarded by the recovery of identifiable eggs particularly if a concentration technique is employed. Even where they cannot be found scrapings, through a proctoscope from those cases with creamy or yellowish pinpoint nodules at or below the recto-sigmoid junction will yield a parasitological diagnosis. Where even this fails, if a diffuse intestinal capillary dilatation can be seen proctoscopically attempted aspiration will rupture the wall of a capillary and the microscopic specimen of blood which exudes may yield a few eggs.

A R D Adams.

DESPORTES C. La dermatite des nageurs. [Swimmer's Itch.] *Ann Parasit Humaine et Comparée* 1944-1945 v 20 Nos 5/6 263-78 1 fig [24 refs]

During the prolonged dry period of October 1944 the author observed foci of snail-infested water at Indre-et Loire. Twelve per cent of these snails were emitting ocellated furcocercous cercariae. Voluntary exposure of the legs on two occasions in infested water resulted in a dermatitis which is described in detail. The beneficial effect of cryotherapy [the use of cold] in alleviating the pruritus is recorded.

In the subsequent section of this paper the literature of swimmer's itch is reviewed and a general study of the disease is set down from the aspects of synonymy definition aetiology pathogeny geographical distribution symptoms clinical picture histopathology diagnosis and individual and general prophylaxis.

J J C Buckley

LARSH J E Jr A Comparison of the Percentage Development of a Mouse Strain of *Hymenolepis* in Alcoholic and Non-Alcoholic Rats and Mice. *J Parasitology* 1946 Feb v 32 No 1 61-3

Seven similar experiments were performed in which a comparison was made of the percentage development of *H. nana* var *fraterna* in alcoholic and non-alcoholic rats and mice. In all but one experiment the alcoholic rats showed percentages of cysticercoid development at least 2-4 times greater than those of non-alcoholic controls. At the same time, alcoholic mice had percentages at least 2.1 times greater than controls in every experiment. These results are interpreted to mean that most young rats as well as mice show a reduced natural resistance to *Hymenolepis* following repeated alcoholization.

LARSH J E Jr The Effect of Alcohol on the Development of Acquired Immunity to *Hymenolepis* in Mice. *J Parasitology* 1946 Feb. v 32 No 1 72-8 [13 refs]

Experiments were carried out to determine the influence of 35 per cent alcohol on reinfection of mice with *H. nana* var *fraterna*. When daily treatment with the drug was not begun until several days after initial infection it had no demonstrable effect on reinfection several weeks later. Thus the action of the immune mechanism stimulated before alcoholization was not interfered with in degree to be measured by the infection method employed. In other experiments in which the drug treatment was given daily for a few weeks before the first infection the results varied with the time interval before reinfection. When this period was one week or 72 hours reinfection was not demonstrated. This probably meant that the alcoholic mice had recovered from debilitation. On the other hand reinfection was demonstrated where only 48 or 24 hours elapsed between infections. In both cases the alcoholic mice showed percentages of cysticercoid development many times greater than those of controls. This indicated therefore that alcohol treatment caused a delayed response to antigenic stimulation but the mechanism for this is as yet unknown.

SANGSTER C. B. Hookworm Disease in Australian Soldiers, with Reports of Cases. *Med J Australia* 1946 Mar. 23 v 1 No 12 385-93 3 figs.

This is an account of hookworm disease among Australian soldiers in New Guinea during nine months in 1943-44 and in Bougainville island during the

first half of 1945 its chief interest is in the detailed description of three acute cases in Bougainville.

In New Guinea the disease was clinically mild and the diagnosis was usually indicated during examination of the blood for malarial or other parasites, or of the faeces for amoebae. In some cases the patient complained of lassitude, abdominal discomfort, dyspnoea on exertion and oedema of the ankles regarded as signs of anaemia. The anaemia was normochromic and normocytic and the haemoglobin was rarely less than 11 gm. per 100 cc. The treatment was tetrachloride 3 cc. together with either tetrachlorethylene 4 cc. or carbon oil of cheneopodium 1 cc. this dose was repeated after 8 days if thought necessary. Ferrous sulphate 3 gm. t.i.d. was given for anaemia. A good diet was supplemented in some cases with vitamins B₁ and C.

In Bougainville the disease was also usually mild but there were three acute cases and some others gave the clinical history of the symptoms of the invasive stage. Ground itch, usually erythematous and vesicular was observed, in different patients from a few minutes to a few days after contact with infected ground. Cough and sore throat with, in some cases bloodstained sputum, appeared after 5 to 7 days and lasted for a month or more. Abdominal discomfort appeared from two to several weeks later, anorexia, nausea, sometimes vomiting and cramps occurred and there was also intermittent diarrhoea treated as for dysentery with sulphaguanidine without effect however. This history was given by 25 patients.

Diagnosis.—In Bougainville both *Ancylostoma duodenale* and *Necator americanus* were present in New Guinea only *Necator americanus* was found. High eosinophilia was observed in blood examinations, an absolute count of over 400 per cmm. being regarded as significant, the highest count was 51 000 (85 per cent). Numerous eosinophils (50 per cent) were also seen in the venacular fluid of skin lesions and the sputum also showed numerous eosinophils.

Acute cases.—These three cases are described in detail throughout the illness. There was severe anaemia and persistent diarrhoea with a considerable amount of blood in the stools was present though hookworm ova were not found for several weeks. Repeated doses of the anthelmintic, mature were required and blood transfusions were needed, one patient receiving a total of over 500 ounces in 12 transfusions. This man had a mixed infection of *A. duodenale* and *N. americanus* while the other two had *N. americanus* only. One of the patients developed an abscess of the lung, another was infested with about 500 hookworms. Examinations of the sternal marrow showed "no lack of maturation and no depression of the erythroblastic series. All three patients recovered after severe illnesses lasting several months. J. F. Corson

DE MEIRA, M. T. V. G. & CORREIA, A. de M. F. Sobre um foco de anquilostomose rural autóctona em Portugal. A Rural Focus of Ankylostomiasis in Portugal. In Inst. Med. Trop. Lisbon 1943 Dec. v. 2, 67-73. English summary.

KARTMAN, L. A Note on Anopheline Vectors of *Wuchereria bancrofti* in West Africa. (Research Notes.) Parasitology 1946 Feb. v. 32, No. 1 91-2.

During the early part (January to May) of 1944 the author dissected *Anopheles gambiae* and *A. funestus* caught in four native villages situated within 12 miles eastward of Dakar, Senegal, French West Africa. The results are seen in the table.

TABLE I
W bancrofti in anopheline mosquitoes from four native villages

Date (1944)	Village	Host	Number Dissected	No filaria found in					Number Infected	Per cent Infection
				Cut	Abdomen	Thorax	Head	Proboscis		
1-15 to 5-17	A	<i>A. gambiae</i>	79	15	0	58	0	1	39	49.3
1-21 to 5-17	B	<i>A. funestus</i>	351	24	0	83	0	0	65	18.5
1-17 to 5-15	C	<i>A. gambiae</i>	23	3	0	2	0	0	3	13.0
1-17 to 5-15	C	<i>A. funestus</i>	82	0	0	2	0	1	2	2.4
5-30 to 6-16	D	<i>A. gambiae</i>	72	61	0	44	9	0	39	54.1
	D	<i>A. funestus</i>	223	28	0	18	0	0	41	18.3
	D	<i>A. gambiae</i>	200	19	3	44	4	0	56	28.0
	D	<i>A. funestus</i>	90	2	3	7	1	0	9	10.0
	D	<i>A. gambiae</i>	374	88	3	148	13	1	137	36.6
Total		<i>A. funestus</i>	740	52	3	90	1	1	117	15.6

These two species were predominant throughout the year far outnumbering all other mosquitoes including *Culex fatigans*. The author states that it has been suggested that *A. funestus* has a lower infection rate than *A. gambiae* because being a smaller mosquito it takes less blood at a feed than *A. gambiae* does.

BEHN A W & HAYMAK J M Jr The Course of Filariasis after Removal from an Endemic Area. *Amer J Med Sci* 1946 Apr v 211 No 4 385-94 3 figs (13 refs)

A report on the condition of men from the American forces invalidated with alleged filariasis from Tonga tabu, an endemic area of Bancroftian filariasis on their arrival in the United States in the latter part of 1943 has already appeared in this Bulletin 1945 v 42, 1020. The present paper is an interim report on the progress of these men (Group A) two years later. It also contains information on a second group (Group B) of 145 men who were exposed to possible infection in Woodlark Island (off New Guinea) and on a further group (Group C) of 32 men who had never been in a filaria endemic zone. Woodlark Island has in the filaria endemic zone but there is no record of a native of the island having been shown to harbour the infection.

In the Tonga tabu cases (Group A) parasites were demonstrated in very few men other laboratory tests were unhelpful and the diagnosis of filariasis was essentially clinical. In the 532 men comprising this group the authors consider that only 186 really had filariasis and that 396 were free from the infection. The intradermal test with a *Dirofilaria immitis* antigen proved of doubtful value in differentiating the uninfected from the infected as false positive reactions were obtained even in the controls (Group C). A history of one or more attacks of mumps (fever lymphadenopathy and retrograde lymphadenitis) with swelling lasting at least one day was regarded as convincing evidence of an infection. Adenopathy alone was of little significance as it was extremely common in the forces in the Pacific islands. In infected persons the symptoms and signs decrease with the passage of time and most of the infected Group A cases were free of symptoms 20 months after leaving the endemic area.

The authors analyse in some detail the clinical findings among the infected and the uninfected men in Group A and compare them with those encountered in the 145 Group B men from Woodlark Island whose infection at best was problematical. They find a striking similarity in the clinical manifestations such as swelling of limbs or the scrotum and adenopathy in the three groups. Owing to the fact that most physicians lacked acquaintance with the disease a diagnosis of early filariasis was often made on quite inadequate grounds even in men who could never have been exposed to infection. The psychological complications of the diagnosis are considerable in view of the (usually ill-founded) fears it engenders and the lack of any specific treatment. The longer an ill-founded diagnosis is allowed to continue the greater the difficulty in restoring the patient to full normality.

WOLFE H. R. I & SCHOFIELD A. L. A Case of Filarial Funiculitis. *Brit. J. Surg.* 1946 Apr v 33 No 132, 395-6 3 figs.

An American Naval Air Gunner aged 25 was stationed in tropical Africa from March, 1942 to May 1944. He arrived back in America on February 10th 1945 and was at once sent to hospital as a case of suspected strangulated

inguinal hernia. On the preceding day he felt a stab of pain in the left groin which he thought was caused by the pressure of his parachute harness as he climbed down from an aeroplane to the flight deck of his ship.

On admission his temperature and pulse rate were normal. The left side of the scrotum was indurated and oedematous but the testicle and epididymis felt normal. The cord was thickened and tender up to the external abdominal ring. He had no other symptoms and torsion of a testicular hydatid or acute funiculitis of unknown aetiology was diagnosed and operation advised.

The cord and testicle were explored through a left inguinal incision. Between the external abdominal ring and the testis the cord had expanded into a firm fusiform mass about the size of a walnut. On incising the tunica vaginalis the testis and epididymis appeared normal. The coverings of the cord were incised and examined. The vas deferens was inflamed and nodular and on its surface were some discrete yellowish nodules 0.5-3 mm. in diameter which on microscopic examination were seen to consist of lymphoid follicles packed with eosinophils and they showed marked lymphangiectasis. The pampiniform plexus was engorged and some of its branches in contact with the inflamed vas were thrombosed. An enormously dilated and varicose lymphatic was found running down to the upper pole of the testis. Through its thin wall the wriggling, white hair-like coils of a worm were seen. It was excised and the worms were identified as *Wuchereria bancrofti*. Convalescence was uneventful and the patient left hospital three weeks after the operation.

CULBERTSON J T ROSE H M & OLIVER-GONZALEZ J Chemotherapy of Filariasis due to *Wuchereria bancrofti* with Neostibosan. *Amer J Hyg* 1946 Mar v 43 No 2 145-51 1 fig

This paper describes the progress of an investigation the earlier stages of which have already been reported [this *Bulletin* 1946 v 43 54 & 354]. Briefly 35 patients with microfilariae in the blood were given neostibosan. Twenty (Group I) were given 4.6 to 10.5 gm in 33-54 days. Ten (Group II) were given the same course as Group I but as this seemed relatively ineffective they were treated again 9 months later with 5.9 to 12.5 gm during 14 days. Five patients (Group III) were treated intensively receiving 9.5-15.5 gm. in 13-14 days. The initial dose was 0.1 gm. injected intravenously later this was worked up to two or three injections each of 0.5 gm. per day.

Of the patients in Group I 15 lost all their microfilariae in various periods up to 15 months after treatment. In three patients the microfilariae were greatly reduced in 15 months and in two patients there was little change in 9 months. In the 10 patients of Group II who had resisted the first course three lost their microfilariae in five months, in six the microfilariae were much reduced, and one showed only slight change. In Group III two patients became microfilaria negative in six months and three lost at least half their microfilariae.

Among 15 control patients none became microfilaria-negative in 14-17 months and 11 showed considerable increase in the number of microfilariae present in the blood. Toxic reactions in the treated patients were relatively light although half the patients experienced nausea and vomiting, two had severe nausea, anorexia and other symptoms but it was not necessary to stop the drug in any patient. None of the treated patients has shown any sign of the development of elephantiasis although such a hazard, as a result of treatment has been suggested by some investigators. It is believed that neostibosan kills the adult worms leaving the microfilariae to disappear slowly from the circulating blood because their number is no longer replenished.

POIG SOLAMES M. FORTES A. & ANTONIO QUITOZ. J. La onchocercosis en el estado de Chiapas. [Onchocercosis in the State of Chiapas, Mexico] Reprinted from *Rev. Salubridad y Asistencia* 1945 July & Aug. No. 10 30 pp. 19 figs.

This investigation into the ocular complications of onchocerciasis was carried out during February 1945 under the auspices of the Pan-American Sanitary Bureau and the Mexican Health Department, in a part of the State of Chiapas where onchocerciasis was known to be endemic.

Ninety three cases were examined, 82 of them proved by the presence of onchocerca nodules (elsewhere the number with nodules is given as 89) or by biopsy tests. One had superficial punctate keratitis regarded as characteristic of the infestation although no nodules were present. Of the 93 there were 64 males 29 females 78 were of mixed race 13 were natives 4 were not noted [but no mention is made of the relative constituents of these in the population so that the racial incidence cannot be stated]. Fifty two were under 20 years of age and 18 below 10 years 17 in the third decade [by ages the total of cases amounts to 92 other discrepancies occur in the tables for example in one the cases over 10 years total 73 not 76]. Onchocerca dermatitis present or past was noted in 19 cases biopsy was positive in 70 (79.5 per cent) negative in 18 (20.4 per cent) of 88 so tested.

The longest section of this contribution is devoted to the ocular symptoms present in this disease. Seventy of the 93 had demonstrable clinical signs one had the embryos in the eye but without clinical signs. In most of the patients eye symptoms appeared in 7-9 years after the earliest indications of infestation and of the 70 65 had nodules and 57 gave positive biopsy findings microfilariæ were found in the eyes of 29 patients. Sixteen presented the typical symptoms of burning smarting and the sensation of the presence of a foreign body. Affection of the cornea was seen in 80 of the 118 in 27 glaucoma secondary to onchocerciasis occurred in one. The commonest lesion of the cornea was a punctate superficial keratitis and refractile filiform opacities of dead microfilariæ and it may be that the death of the embryos was the real cause of the keratitis. This keratitis, strange to say affected but slightly the acuity of vision. Of 81 examined, the vision was 10/10 in 45 8/10 in 9. The iris evolves very slowly but seriously affects visual acuity. Of 18 with this complication only two had normal vision, one had not even perception of light and 14 others had vision 1/20 or less. Lesions of the fundus were very rare the greater frequency in African patients is ascribed to the existence of other diseases such as tuberculous, syphilis or trypanosomiasis. An additional reason must not be left out of account patients in African records had had no treatment whereas the majority of those studied in the present investigation had undergone periodical removal of nodules.

H Harold Scott

CORVEN H. H. Trichinosis as a Cause of Neuralgia Paraesthesia. *J Bone & Joint Surgery* 1946 Jan v 28 No 1 153-6 3 figs

Neuralgia paraesthesia is characterized by alteration of sensation pain or diminished sensation on the antero-lateral aspect of the thigh on walking or by contact with clothing and is ascribed to neuritis or to pressure on the external femoral cutaneous nerve. It has been found associated with pressure from a belt or corset. The nerve runs close to the anterior superior iliac spine and passes over or under the sartorius and pressure may thus be caused by an abnormally placed fibrous band.

The case here described is that of a man 42 years of age who had suffered for 4 years from numbness of this area with pins and needles and hot and cold sensations. Walking increased the symptoms and often caused pain. Operation revealed that the nerve in question was being compressed by a dense fibrous band. Immediate relief was obtained by excision of this band. Section of the tissue removed revealed numerous cysts of *Trichinella spiralis* but none of them calcified. A history was obtained of the patient having a year before the onset of these symptoms eaten pork and suffered after the meal from fever and diarrhoea. [There is no doubt of the association of the trichiniasis with the symptoms but to what degree the parasite was aetiologicaly responsible is less certain. The fibrous band was present but this may be so in the absence of any *Trichinella spiralis*.] H. Harold Scott

AYERA J W, YOW E M, HARRELL G T & FOWLER Elizabeth B. An Attempt by Feeding to Induce in Animals Reactivity to *Trichinella spiralis* in the Absence of Infection. *Amer J Trop Med* 1946 Jan \ 26 No 1 125-31

HARRELL and HORNE *Bulletin of Hygiene* 1945 \ 20 469 found a significantly higher incidence of positive skin tests done with *Trichinella* antigen among patients in tuberculosis sanatoria and in hospitals for mental disease than among subjects in general hospitals. The length of stay in the institution seemed to be significant but that study provided no evidence of the existence of unrecognized institutional epidemics of trichiniasis. THIBERGE (*J Allergy* 1944 \ 15 298) reported that antigens contained in pollens can cross the mucosal barriers of the intestine and can cause symptoms in allergic subjects. If the sensitizing agent can cross the intact mucosa ingestion of meat containing killed larvae of *Trichinella* might cause sensitivity. Cooking might denature the protein of *Trichinella* but meat frozen to make it non-infective could be so incompletely cooked that the antigen might be unaltered. This might explain the high incidence of positive skin tests done on subjects in institutions. The present study was made to find out whether positive skin tests could be produced in animals not infested with *Trichinella* by the ingestion of killed *Trichinella*. It showed that this did not happen and that the hypothesis just suggested did not explain the high incidence of positive skin tests in subjects in institutions. For details of the experiments the original should be consulted.

Discussing their results the authors say that SPINDLER and CROSS (*Proc Helminth Soc Wash* 1939 \ 6 37) reported that skin sensitivity could be acquired by hogs by eating scraps of pork containing non viable larvae of *Trichinella* and that SCHWARTZ in a personal communication told them that hogs fed with cooked trichinized meat for several weeks gave weakly positive intracutaneous reactions to *Trichinella* antigen although no trichinellae could be found in them. The present authors have been unable to reproduce this phenomenon in the guinea-pigs and rabbits which they used. The skin tests and flocculation tests recorded in this paper failed to show that animals fed with trichinized meat reacted to the antigens nor did meat containing *Trichinella* larvae killed by freezing in order to avoid denaturation of the *Trichinella* protein produce positive skin or flocculation reactions. The present authors have not tried to find out whether the digestive juices of herbivorous animals can inactivate antigens of killed *Trichinella* although THIBERGE (*loc. cit*) states that ingested pollen is inactivated by the gastric digestion of man. The authors think that because the degree of allergy in trichinosis individuals is high the passage of undenatured *Trichinella* antigen across the mucosa

might cause vague symptoms which might be attributed to allergy to pork but are really due to allergy to the parasite contained in the meat. This mechanism might be responsible for the high incidence of *Brucella* skin tests because antigen which has passed the mucosal barrier might produce sensitivity without infection.

Contrary to reports in the literature [see BACHMAN this Bulletin 1929 v 28 551] the authors were unable to produce strongly positive skin reactions to 1:200 dilutions of *Trichinella* antigen in guinea-pigs known to be infected. They consider that rabbits are better than guinea-pigs for skin and flocculation tests. The most clear-cut skin reactions were however obtained in the infected dog used and the authors suggest that rabbits, or preferably dogs, should be used rather than guinea-pigs for future skin tests. The authors cannot explain why the flocculation tests were not clearly positive in the infected guinea-pigs. No precipitin tests were done for comparison with them but the flocculation test gave positive results in infected rabbits and detected an extremely mild degree of infection in one rabbit. The technique of this test is however tricky and needs large amounts of dried and powdered larvae. In its present stage of development it is probably not applicable to large-scale work, although it gives promise of being useful for the diagnosis of suspected cases.

DEFICIENCY DISEASES

HUGHES W. Kwashiorkor and Ariboflavinosis. *Trans Roy Soc Trop Med & Hyg* 1946 Apr v 39 No. 5 437-48 8 figs. on 4 pls. [18 refs.]

In Lagos three fairly well-defined syndromes of malnutrition may be distinguished—simple ariboflavinosis, kwashiorkor and nutritional achromotrichia. These are not rigidly distinct—simple ariboflavinosis, characterized by lesions of mouth, tongue and external genitals, is commonest among adults. Rare cases, however, occur in children and these constitute a link between the adult syndrome and kwashiorkor. Achromotrichia appears to be a separate condition in which mucocutaneous lesions are minimal. It may be present in some cases of kwashiorkor but alopecia is more common. It is suggested that nutritional achromotrichia may be caused by pantothenate deficiency.

The description that follows is based on the findings in 65 cases of kwashiorkor. Nearly half of these patients were two years old or less, although some cases were seen up to the age of 9 years. With increasing age the mortality and severity declined and the condition merged into the simple ariboflavinosis of adults. It is argued that in kwashiorkor the epithelial lesions are essentially similar to those of adult ariboflavinosis, but more widespread, and more severe. The two conditions may perhaps be best contrasted in a table constructed from the author's data.—

	<i>Adult Ariboflavinosis</i>	<i>Kwashiorkor</i>
Mouth	Glossitis cheilosis angular stomatitis	Glossitis cheilosis angular stomatitis
Face	Seborrhoeic lesions in naso-labial folds at canthi etc.	Fissures in naso-labial folds at canthi, above ears
Perineum	Dermatitis of scrotum	Scaling and exfoliation of prepuce scrotum, vulva and whole of perineum. Fissures and depigmentation.
Other parts	Typically no change	Desquamation and exfoliation on extensor surfaces of limbs dorsa of hands and feet, tips of nose and ears. Depigmentation and fissuring in flexures.

Many of the lesions listed above are illustrated by excellent photographs. Microscopically the skin showed parakeratosis and acanthosis.

Other features of the disease were lethargy, anorexia, muscular wasting, bradycardia, anaemia, oedema, and signs of dehydration with oliguria. In four cases there was an abrupt and unexpected lapse into coma and death. At post mortem examination the outstanding feature was fatty infiltration of the liver. The more the cases approached the typical the more intense the fatty change.

The author points out that in experiments on riboflavin-deficient dogs SEBRELL [*Bulletin of Hygiene* 1930 \ 5 374] observed sudden death in coma, and a fatty liver post mortem. These findings supported the view that kwashiorkor might be a result of ariboflavinosis. However the results of treatment were disappointing—riboflavin in doses of 10 mg parenterally rapidly cured the lesions of mouth and perineum, but it did not prevent death. Crude liver extracts seemed to produce some beneficial effect particularly an improvement in appetite. In many cases death was precipitated by concomitant disease such as malaria, tuberculosis or septicaemia.

Summarizing the author states that it is something if we can recognize and follow the thread of riboflavin deficiency through the complicated pattern of kwashiorkor. The severe case is probably suffering from many other deficiencies consequent on inanition. Even if the final hepatic lesion is the consequence of inanition and quite beyond the influence of B₂-complex therapy it will not alter the position from the preventive point of view. It is suggested that for prevention attention should be concentrated on making available supplies of the B₂-complex and that a practical source of this is food-yeast in a dosage of 10 grammes daily.

[In the treatment of kwashiorkor nicotinic acid has been no more successful than riboflavin. Neither appears to have any effect on the liver lesion. The experimental evidence for the production of fatty liver by deficiency of B₂ vitamins except choline is slender. The liver lesion described by SEBRELL (*loc cit*) appears to be histologically different from that of kwashiorkor. On the other hand there is much experimental evidence that a fatty liver can be produced by protein or amino-acid deficiency and some clinical evidence that a high protein diet has a good effect on the liver in kwashiorkor. The recommendations made here for prevention must be examined in the light of this possibility—that the liver damage is not irreversible, and that it is the result of deficiency of protein or its derivatives. The recommended daily dose of 10 grammes of food yeast would supply 4 grammes of protein.]

J C Waterlow

HUGHES W. Food Yeast in Tropical Malnutrition. *Lancet* 1946 Apr 20 569-72.

Feeding trials with food yeast were carried out on prisoners and lunatics in Nigeria. In both these groups signs of riboflavin deficiency were very common.

Tropical Diseases Bulletin.

being found in 25-30 per cent. of subjects examined. Four grammes of food yeast were given daily for five weeks to a group of 18 prisoners with severe signs of deficiency. At the end of this time the number with lesions was reduced to five of whom only one was severely affected. During the following three weeks when no yeast was given, six patients relapsed. In a control group of untreated prisoners there was no change in the incidence of severity of the lesions.

In a second experiment, 145 male lunatics received 8 gm. of food yeast daily for seven weeks. The number of cases with signs of riboflavin deficiency fell from 45 to 18 and the severity of the lesions decreased. In a control group of female lunatics who did not get yeast, there was no change in the incidence of lesions, and the severity increased. In a similar trial on prisoners, 8 gm. of yeast were given daily for eight weeks. Out of 64 cases with signs of riboflavin deficiency 58 were cured.

It is concluded that 10 grammes of food yeast daily would be enough to prevent manifestations of riboflavin deficiency in the population of Lagos. This amount of food yeast contains about 0.5 mgm. of riboflavin.

No estimate is given of the riboflavin content of the average Nigerian diet, so that it is not possible to see how far the recommended supplement of 0.5 mgm. goes towards filling the gap between actual intake and optimum requirement. Adequate nutrition is not necessarily achieved with the correction or prevention of clinical deficiency.]

SMITH T D & MOREY Mabel M. A Clinical Study on the Use of a Protein Supplement in treating Persons with Nutritive Failure. *Southern Med J* 1946 Feb v 39 No. 2, 117-21 5 figs.

In the last few years it has gradually though rather tardily been recognized that in the clinical conditions we call deficiency diseases the deficiency is one of several nutrient factors and that these include not only the so-called vitamins—in other words the term deficiency disease is not synonymous with hypovitaminosis. The authors say we are becoming increasingly aware of the extent of the protein deficiency in many diets and its role in nutritive failure. We are studying not only the effect of individual amino acid on persons with deficiency diseases but also the effect of complex concentrated proteins such as hydrolyzed casein.

The case histories of two patients selected from a group of 16 with pellagra and anaemia and oedema are given to illustrate the effect of the latter. The administration of hydrolysates appeared to clear up the oedema and in some cases the cheilosis which had proved resistant to riboflavin.

Apart from the attempt to show experimentally the specific effect of protein hydrolysates on certain symptoms it would appear that these have no advantage over a correct diet containing meat, milk and eggs.

H S Slatkowsky

GOPALAN C. The "Burning Feet" Syndrome. *Indian Med Gaz.* 1946 Jan. v 81 No 1 22-8

The author gives an excellent description of the syndrome burning feet—Kai erichal, in Tamil—well known to medical men who have had opportunities for making observations among indigenous populations during the past half century. He quite correctly states that the condition should be clearly distinguished from peripheral neuritis and beriberi with which it has often been confused by authors whose observations have not been made with sufficient care.

This article is based on 53 cases 14 males and 39 females from among a poor population living on a parboiled rice gruel and cheap vegetables. Among the women 27 gave a history of parturition within a few weeks of being seen.

In practically all the patients signs of riboflavin deficiency were present—glossitis angular stomatitis angular blepharitis in some superficial keratitis was present in a fair proportion of the males scrotal dermatitis was noted and in the women leucorrhoea was present [no slit lamp examinations apparently were made]

The burning pain commonly began in the region of the ball of the big toe then spread over the sole and sometimes involved the dorsum of the foot and ankle less often the palms of the hands were involved.

Some cases were seen in which excruciating paroxysms of burning pain alternated with freedom from it. Associated with this symptom sensations of pins and needles were complained of as noted by other observers but the two did not necessarily parallel each other.

Hyperidrosis another well known symptom of the syndrome was noted as occurring in the areas of burning pain. On the other hand there was no muscular wasting or tenderness no loss of power no paralysis no spasticity no loss of reflexes no sensory loss of any kind.

There was no response to thiamin or nicotinic acid. Treatment with riboflavin while clearing up the signs of hyporiboflavinosis left unchanged the burning pain syndrome. Rapid improvement and cure however followed upon the daily intramuscular injection of 20 to 40 mgm. calcium pantothenate for 2-3 weeks in 10 cases submitted to the treatment.

In discussing the pathology [pathogeny] of the condition reference is made to the abridged version of the Lunnleian Lectures for 1944 [this *Bulletin* 1944 v 41 862] in the following words. Stannus (1944) has indeed suggested that burning feet is part of the syndrome of ariboflavinosis. [This is of course incorrect as throughout those lectures—entitled Some Problems in Riboflavin and Allied Deficiencies—it was made clear that the syndromes described were due to a hyporiboflavinosis alone or associated with a deficiency of another closely allied factor of the B complex.] In further discussion no fresh data are supplied and no definite conclusions are reached in regard to pathogeny.

H S Stannus

SPRUE.

SPIES T D MILANES F MENÉNDEZ A. KOCH Mary B & MINNICH Virginia
Observations on the Treatment of Tropical Sprue with Folic Acid. *J Lab & Clin Med* 1946 Feb v 31 No 2 227-41 4 figs.

Nine patients suffering from tropical sprue were treated, under standardized conditions with folic acid by mouth in dosage ranging from 10 to 200 mgm. daily. The response of those receiving only 10 mgm closely paralleled that of those receiving higher doses and was manifest by a rapid improvement in each patient's feeling of well-being an increase in appetite a gain in weight and strength a decrease in the pigmentation of the skin together with resolution of the glossitis soreness of the mouth and burning of the rectum. This clinical improvement was accompanied by a striking haematological improvement. In all cases a maximal reticulocytosis occurred, the day of the peak ranging from the sixth to the ninth day which was followed by rises in the red cell count varying from 0.50 to 1.21 million per cubic millimeter in 14 days in the patients receiving 200 gm. folic acid, and from 0.46 to 0.71 million in those

[August 1946]

receiving 10 mgm doses. The haemoglobin levels of all the patients increased as the erythrocyte counts increased while the leucopenia generally accompanying the macrocytic anaemia decreased. Normal control subjects receiving 200 mgm. folic acid orally for ten days showed no changes in their erythrocyte counts haemoglobin levels, leucocyte counts or in the number of reticulocytes in the four weeks following the administration of the drug. The bone marrow of the patients with sprue treated with folic acid, showed macroscopically a gross change from light red, thick gelatinous marrow to deep red fluid containing discrete clumps of cells and macroscopically the erythroblastic arrest of the disease was replaced by a normoblastic hyperplastic regeneration, with a shift in the ratio of white cells to nucleated red cells from 5:2 to 5:6.

The paraesthesiae of the hands and feet were not markedly affected by the administration of folic acid but the oedema disappeared in all but two patients. The diarrhoea followed a variable course, gradually decreasing in most cases, although in some the faeces failed to improve while in others initial improvement would sometimes be followed by reversion for a day or so to copious frothy stools. (See also Series below) F. Mergelroyd.

DARBY W. J. JONES, E. & JOHNSON, H. C. Effect of Synthetic Lactobacillus Casei Factor in Treatment of Sprue. *J Amer Med Ass* 1946 Mar 23 v 130 No. 12, 780-88 7 figs [Refs. in footnotes]

A deficiency syndrome in the monkey characterized by anaemia, leucopenia, diarrhoea, oral lesions, facial oedema, loss of weight and death can be prevented by a factor sometimes referred to as vitamin M, which has been differentiated from nicotinic acid, riboflavin, thiamin, pantothenic acid, choline, para-aminobenzoic acid, pyridoxine and inositol. Certain purified liver extracts which were effective in the treatment of pernicious anaemia also failed to prevent the nutritional cytopenia in the monkey. Monkeys deficient in vitamin M respond, however, to the intramuscular administration of small quantities of a highly purified *Lactobacillus casei* factor and the various similarities of vitamin deficiency in the monkey to the sprue syndrome in man led to a test of the efficacy of the newly synthesized *L. casei* factor in the treatment of three patients suffering from sprue.

The patients were maintained on standardized diets devoid of organ meats, and the crystalline *L. casei* factor was given intramuscularly in a dosage of 15 mgm daily. The response of the patients resembled that following the administration of an active liver preparation. Within two or three days all the patients experienced a feeling of improvement. The glossitis was relieved by the fourth or fifth day and simultaneously there was a cessation of the diarrhoea and an increase in appetite. A gain in weight commenced on approximately the fifth to the seventh day, the initial gain apparently reflecting water retention as it was accompanied by demonstrable oedema and haemodilution which disappeared about the twelfth to the fourteenth day. Subsequent to this the patients did not show a striking increase in weight unaccompanied by water retention. Although the diarrhoea was promptly relieved, stool analyses did not return to the normal fat content while furthermore the patients did not exhibit an increase of fat within the gastrointestinal lumen.

The treatment brought about increases in all the formed elements of the blood and the bone marrow which prior to treatment showed a megaloblastic arrest, returned to normal ten days after administration of this *L. casei* factor will result in a satisfactory response in cases of sprue, pernicious anaemia, macrocytic anaemia of pregnancy and nutritional macrocytic anaemia. Unpublished data.

indicate that the factor is effective only in those macrocytic anaemias with hyperplastic primitive marrow so-called dysplastic and aplastic anaemias failing to respond even though examination of the peripheral blood indicated a macrocytic anaemia.

From the relationship outlined the authors suggest that vitamin M deficiency in the monkey is the experimental analogue of sprue in man. As the term folic acid has been so loosely used they feel that its retention can but lead to confusion and they propose that the group of substances which possess similar haematopoietic activity for primates be referred to as the vitamin M group [see SPIES this *Bulletin* 1946 v. 43 582 SPIES *et al.* above]

The doses given to the patients in these experiments are probably in excess of the minimal amount which would produce a maximal response. A reticulocyte response has been reported in two patients suffering from pernicious anaemia who were given intravenously only 2 mgm. daily and from a comparison of the requirements of chicks for riboflavin and the *L. casei* factor it is suggested that in man the maintenance dose of the *L. casei* factor may be of the order of 0.1 to 0.2 mgm. daily and that the curative dose may be about 1 mgm. daily. No local or systemic toxic effects were however observed from the administration of the material in the doses employed to 12 persons manifesting a variety of blood dyscrasias. [See also this *Bulletin* 1946 v. 43 667] F. Murgatroyd

HAEMATOLOGY

SPIES T. D. Effect of Folic Acid on Persons with Macrocytic Anemia in Relapse
J Amer Med Ass 1946 Feb 23 v. 130 No. 8 474-7

Folic acid was given parenterally or orally in amounts of 20 mgm. or more daily to 45 patients suffering from anaemia, including 8 patients with nutritional macrocytic anaemia, 8 with pernicious anaemia, 11 with sprue, 3 with anaemia associated with pregnancy, 1 with anaemia associated with carcinoma, 1 with anaemia associated with chronic alcoholic addiction, cirrhosis of the liver and neuritis, 3 with anaemia of undetermined origin, 3 with aplastic anaemia, 3 with anaemia associated with leukaemia, and 4 with iron deficiency anaemia. None of the patients with aplastic anaemia, iron deficiency anaemia, or the anaemia associated with leukaemia showed any improvement but there was a very marked subjective and objective improvement following the administration of folic acid to those suffering from macrocytic anaemias. These latter patients experienced an immediate feeling of improvement together with an increase in strength, vigour and appetite. This subjective improvement coincided with or was followed by an increase in the reticulocytes of the peripheral blood and by subsequent rises in the red blood cell counts and in the haemoglobin content of the blood. This improvement occurred regardless of the mode of administration of the drug. The minimal and optimal doses of folic acid have not yet been determined and there appears to be some variation from patient to patient. It has been found however that while 400 mgm. daily may be administered without untoward symptoms as little as 5 to 10 mgm. parenterally or 10 mgm. orally each day will often produce a maximal haematopoietic response. It has also been found that patients failing to respond fully to 3 to 4 mgm. folic acid daily may respond to liver extract or yeast administered in amounts which supply only 1 mgm. or less of folic acid daily which suggests that the antianemic factor present in liver extract or yeast may be a combination of chemical substances.

SMITH T. D. VILTER, C. F. CLINE, J. K. & FROMMEYER, W. B. The Substitution of Thymine for Folic Acid in the Treatment of Macrocytic Anaemias in Rabbits. *Southern Med J* 1946 Mar v 39 No. 3 268-70 [12 refs.]

It has been shown that thymine (2, 4-dihydroxy-5-methyl-pyrimidine) an integral portion of cells, and occurring as part of nucleic acid, could replace folic acid as a growth factor for lactic acid bacteria provided that other essential substances, including adenine, guanine, or xanthine were present, but the amount of thymine required was 5,000 times as great as that of folic acid. It was suggested that folic acid acts as an enzyme or coenzyme in the synthesis of thymine or a thymine-like compound which is used by the bacteria to form nucleic acid.

If this represents a fundamental biochemical mechanism of cellular activity it is possible that thymine might replace folic acid in the maturation of the cellular elements of the blood, and the amount of thymine required might be of the order of 12.5 to 25 gm. daily since some patients with macrocytic anaemia respond to as little as 2.5 to 5 mgm. of folic acid daily.

Six patients with nutritional macrocytic anaemia and the anaemia of sprue showed no response to thymine in doses of 5 to 50 mgm. daily for ten days. One patient given 500 mgm. twice daily for six days also showed no response but when the dose was increased to 2 gm. thrice daily for 14 days a reticulocytosis of 14.2 per cent was reached on the eleventh day and concomitant decrease in the symptoms referable to the glossitis. The erythrocytes also rose from 2.01 million to 2.74 million and the haemoglobin from 6.3 gm. to 9.4 gm on the twentieth day of the treatment with the large dosage. Thereafter without further treatment the reticulocytes subsided but the erythrocytes increased to 2.83 million and the haemoglobin to 10.4 gm while the bone marrow reverted from a condition of megaloblastic arrest to normal.

COOPERMAN, J. M. ELVERJEM, C. A. McCALL, K. B. & REEGANER, W. R. "Folic Acid" Active Compounds in the Nutrition of the Monkey. *Proc Soc Exper Biol & Med* 1946 Jan v 61 No 1 92-7 2 figs. [13 refs.]

A nonite eluate concentrate extractable from yeast or from liver extract, appears to contain at least three factors, namely: folic acid necessary for the growth of *Lactobacillus casei*; vitamin B₁₂ necessary for normal feathering in chicks; and vitamin B₉ necessary for normal growth in chicks. A crystalline compound which has properties similar to those of this concentrate, and which has been called vitamin B₉, can be isolated from liver while a vitamin B conjugate has been isolated from yeast and is active for the chick but has no activity for the bacterium. Upon enzymatic digestion, however, this B₉ conjugate becomes active as a source of B for *L. casei*.

A deficiency of folic acid in monkeys leads to a syndrome, a prominent feature of which is leucopenia, and experiments showed that crystalline B and a synthetic L. casei factor were active in doses of 100γ daily that the B₉ conjugate was less active in doses of 200γ and 300γ daily and that B₁₂ and B₁ concentrates were inactive as sources of folic acid. The folic acid deficiency also precipitates a deficiency for the monkey anti-anaemic factor and a reversal characterized by lack of growth a suboptimal haemoglobin level and a reduction in the neutrophil-lymphocyte ratio. While B₉ conjugate, B₁₂, and the synthetic L. casei factor were effective in raising the leucocyte count the addition of whole liver was necessary to correct the neutrophil-lymphocyte ratio the low haemoglobin level, and the loss in weight.

GIBSON, Q. H. & HARRISON, D. C. An Artificial Standard for Use in the Estimation of Haemoglobin. *Biochem J* 1945, 39 No 5 490-97 [15 refs.]

A satisfactory standard for general use in haemoglobinometry should be reproducible, stable, easily prepared, and have an absorption spectrum closely similar to that of the blood derivative with which it is to be compared. These requirements appear to be fulfilled by a standard solution of a mixture of organic salts prepared according to the following directions—Weigh out 11.61 gm. of $\text{CrK}(\text{SO}_4)_2 \cdot 12 \text{H}_2\text{O}$ (Analar) using crystals free from any sign of whitening due to efflorescence, 13.10 gm. of anhydrous CoSO_4 or the equivalent weight of the hydrated salt and 0.69 gm. of $\text{K}_2\text{Cr}_2\text{O}_7$ dissolve in about 500 ml of distilled water add 1.8 ml of $\text{N H}_2\text{SO}_4$ and heat to boiling. Boil for 1 minute cool well and make up to 1000 ml with distilled water. A more precise method of preparing the standard is also described but solutions prepared by the simplified method given above show readings in the absorptiometer in close agreement with those shown by the precise standard. The standard should be stored in a glass-stoppered bottle free from grease and organic material and ethanol or acetone should not be used for drying apparatus used to contain the standard.

For the routine determination of blood haemoglobin pipette 10 ml of a clear solution of 0.1 N NaOH into a dry boiling tube fitted with a loosely fitting ground-glass stopper ordinary corks must not be used as they give a colour with the alkali. Pure NaOH (Analar) should be used as some impure samples of NaOH give an opalescence when heated with blood and the solution should be stored in a Pyrex vessel. Add 0.1 ml. of blood stopper and mix gently for a few minutes until the solution is clear. Take about the same volume of standard in a similar tube and immerse the two tubes with the stoppers loosened in a vigorously boiling water bath so that the solutions in the tubes are just below the level of the water. Heat for exactly 4 minutes after which at once cool thoroughly by immersion in cold water and mix by inversion. The haemoglobin can then be determined by visual comparison of the two solutions in a colorimeter preferably with a green filter over the eyepiece the haemoglobin value of the standard being taken as 16.0 gm./100 ml. using filters and 16.2 gm./100 ml using unfiltered light. With standardized light and filters the determinations may be made with a photometer or a photoelectric absorptiometer.

The systematic error involved in using the standard as described should not exceed ± 1.5 per cent i.e. ± 0.2 gm of haemoglobin/100 ml. in a normal blood and in view of the variability of blood samples from the same individual it would appear that no practical advantage would be gained from a greater degree of precision.

During determinations of haemoglobin by various methods a consistent difference was found between the values calculated from Fe determinations and oxygen capacity measurements of normal blood. The difference was not due to the presence of carboxyhaemoglobin or methaemoglobin nor due to neglect of plasma iron but indicated the presence of some 3 per cent of iron in a non functional form in normal blood. *F. Margatroyd*

DEWHURST, A. E. The "Cooke-Ponder Lobular Neutrophil Count on the East African Askari. *East African Med J* 1946 Feb, 23 No 2 47-50

The usual procedure for classifying the neutrophil leucocytes into their different maturity groups consists of determining the various percentages of

the cells having one two three four and more than four lobulated nuclei as shown in 100 consecutive cells of a thin film stained by Giemsa's method. The criterion of separate lobulation is that either the lobes appear detached or are joined only by a thin filament of chromatin if there is any doubt about the number of nuclear lobes the cell should be classified in the lower class. Various indices are used to express the results of such a count, the commonest being the Arneth Index, which is obtained by adding the percentages of cells in the first second and one-half of the third class. Another method of expression is by the weighted mean of the percentage counts, a figure obtained by multiplying the number of cells in class I by 1 the number in class II by 2, and so on to class V the sum of the figures so obtained being then divided by the total cells counted namely 100. A higher Arneth Index than 58.5 or a lower weighted mean than 2.75 is taken to indicate a shift to the left from the normal for Europeans. Such shifts have been found in routine surveys of bloods from Egypt Malaya and China.

The present paper records the results of a survey of 500 apparently healthy indigenous East Africans drawn from the following tribes, Jajao Kikuyu Baganda and Mumuwere. No significant tribal differences were noticed and for the total survey the results were — neutrophils of class I 14 per cent class II 41 per cent class III 36 per cent class IV 8 per cent and class V 1 per cent giving an Arneth Index of 73 and a weighted mean of 2.4. If no shift to the left be claimed until the Arneth Index exceeds the extreme limit of the European mean of 58 the following results were found — obtained from the European mean of 58 the following results were found — 18 per cent of the Africans had no shift to the left (Arneth Index below 65) 17 per cent had a very slight shift (A.I. 65-70) 40 per cent had a moderate shift (A.I. 70-80) and 25 per cent had a marked shift (A.I. over 80). The shift to the left in the Africans was chiefly due to a marked increase in the cells of class II, namely the newly segmented neutrophils of the peripheral blood. F. Murgatroyd

BERT E. A. Sickle Cell Disease in the Balovale District of Northern Rhodesia.
East African Med J 1946 Mar \ 23 No. 3 75-88 1 map

Using vaseline-sealed cover-glass preparations of capillary blood examined at intervals up to 48 hours the author found that the overall incidence of the sickle cell trait in 815 consecutive in-patients of the Government Hospital at Balovale an isolated rural area of Northern Rhodesia, was 12.9 per cent. The incidence among males being 12.5 per cent and among females 13.3 per cent. The incidence of the condition among children that is among those under approximately five years of age was 17.6 per cent whereas for those above this age the incidence was only 12.1 per cent. A few patients were examined for sickling in vitro but the condition was not so demonstrated. Some were also examined for the trait by the method of sealing citrated blood under paraffin in test tubes with fixation of the cells by the addition of formalin at the end of 48 hours to obtain the best results it was found that the citrate solution should be boiled before use in order to expel all air.

It was difficult to assess the amount of anaemia due to sickle cell disease as 48.7 per cent of the population harboured hookworms 22 per cent *S. haematobium*, 2.5 per cent *S. mansoni* while in addition at the height of the rains in February 92 per cent of the children under five years of age had malaria parasites. The incidence of helminthiasis was the same among patients with or without the sickle cell trait but it was found that when the transmission of malaria was at its lowest the parasite rate for sicklers was considerably less

than for the non sicklers whereas the rates were approximately equal for sicklers and non-sicklers at the height of the rains when malaria was most prevalent.

The familial character of the sickling cell phenomenon was confirmed as the incidence of the trait among the offspring of a group of 33 affected parents was 65 per cent but there was no evidence that the trait was sex linked.

The Balovale District can be divided into seven areas and study of the incidence of the sickle cell trait in these and adjacent areas suggests that there have been little if any movements of populations within the District from east to west during recent years that there has been considerable emigration of Portuguese natives into the land east of the Zambesi River but little into the land west of the River and that the amount of emigration of Northern Rhodesian Lovale resident west of the River over to the east bank has been small compared with that from the north by the Portuguese Lovale into the same part of the District. This last conclusion is unexpected although the others are more or less borne out by what is known of the history of the District. No detailed investigation of the origin of the Lovale now residing east of the Zambesi has ever been made however and in view of the haematological findings it is suggested that an investigation of this nature should be undertaken since definite information on the point would have administrative value.

VENOMS AND ANTIVENENES

SOBRINHO O P Anaveneno e o seu valor na produção de soros anti
ofídicos [Anavenene for preparing Antisera against Snake Venoms.]
Arquivos do Inst Químico-Biol Estado e Minas Gerais 1945 v 1 27-32
English summary (5 lines)

In 1936 the method of production of antivenenes was to prepare a stock venene consisting of venom 10 gm. glycerin 80 cc. normal saline 120 cc. For stock *Bothrops* venom a mixture was made of *B jararaca* 6 gm and 1 gm of each of *B alternata* *B beuvelandi* *B atrox* and *B jararacussu* in 0.75 per cent saline and fragments of camphor were added to preserve it. This was left at room temperature for a month with daily shaking. It was then injected subcutaneously twice weekly into horses starting with a dose of 0.075 mgm. and by the 25th injection the dose had reached 350 mgm. the total period of immunization was about three months. To obtain a more potent serum 13 more injections were made till at the 38th a dose of 1 000 mgm was injected.

Another method has more recently been put into operation for the use of anavenene. For preparing this 13.33 gm. of the venom are triturated with 333.33 cc glycerin 13.33 cc formol and saline to make a litre the mixture is placed in a thermostat at 37°C for 40 days and then filtered. Horses were inoculated subcutaneously with this 42 injections in 245 days starting with 0.005 mgm. and increasing gradually to 0.450 mgm. The first 14 injections were given every four days after that once a week. The serum so obtained was very satisfactory neutralizing 1.5 mgm. of the venom [per cc. ?] Later still using a preparation containing 10 gm of venom, 330 cc. glycerin and 10 cc. formol the period of immunization was reduced by eight weeks. One great drawback to this method is the frequency with which abscesses follow inoculations but these are in most instances sterile which is not the case when venom itself is used.

H Harold Scott

- MARTINS A V. Sobre o uso do anaveneno na produção do soro anti-escorpionico. [Anavenene in the Production of Scorpion Antivenene.] *Arquivos do Inst. Químico-Biol. Estado de Minas Gerais* 1945 v 1 7-18 [10 refs.] English summary.

NAGALÃES in 1908 prepared a serum against scorpion venom by injecting intravenously into oxen increasing doses of scorpion venom and using camondongos as his test animals. The author has modified this method in each particular. He uses the horse instead of the ox, the anavenene in place of the venom, subcutaneous inoculation in place of intravenous, and guinea-pigs instead of camondongos. His objections to the ox are that the amount of serum obtained is less than that from the horse, that ox-serum is relatively toxic to some laboratory animals and to man, that there is a risk of anaphylaxis to those sensitized to beef protein, and, lastly, the horse is a more docile animal for these injections. The use of anavenene is preferable to venom because its toxicity is much reduced while its antigenic potency is retained. Guinea-pigs are easier to rear and to maintain than are camondongos.

The horses were inoculated every 6-7 days with increasing doses of the anavenene of *Tityus serrulatus* and tests were made after the 8th-9th injections others after the 7th and 15th.

The author claims, and his protocols support the claim, that by his method he obtains much larger amounts of antivenene which moreover has greater antitoxic potency and is produced in less time than by the older mode of procedure.

H. Harold Scott

- MARTINS A V. Anaveneno escorpionico [Scorpion Anavenene.] *Arquivos do Inst. Químico-Biol. Estado de Minas Gerais* 1945 v 1 19-26. English summary (5 lines).

The preparation of scorpion antivenene by repeated injection of the venom into animals has several drawbacks. The author consequently tried using the anatorcin (anavenene) to determine whether it would prove as useful in preparing scorpion antivenene as the corresponding product had proved serviceable for snake antivenenes. He found that by addition of tolual in gradual quantities to form a layer some 5 mm. thick over the venom contained in dark-coloured vials and kept at 4°C. the venom could be preserved for several months without loss of toxicity. If kept at 37°C. its toxicity was reduced to one-sixth in six weeks.

He next found that addition of 1 per cent. formal to the venom and maintaining the mixture at 4°C. reduced the toxicity to about one-tenth without affecting its antigenicity.

H. Harold Scott

DERMATOLOGY AND FUNGUS DISEASES

- GOLDBERG L. C. An Unusual Lichenoid Dermatitis. *J. Amer. Med. Ass.* 1946 Mar 23 v 130 No 12 775-80 10 figs.

This is another report concerning the lichen planus-eczematoid dermatitis complex which has been described on several occasions in American literature, and which has received attention in the British medical press [see this *Bulletin* 1946, v 43 148-301 478].

Except in regard to therapy Goldberg has little new information to add. His observations are based upon a large number of patients returned, because

of this malady to the United States from the South Pacific Theatre of Operations and geographically similar areas. Like other authors he describes phases of dermatitis exfoliative dermatitis and lichenoid eruptions which may occur during the course of the disease. He states that he has never seen a classical lichen planus papule with Wickham's striae in an original case although such lesions have been seen in three relapsing cases. The typical lesion of the lichenoid phase is similar to that occurring in hypertrophic lichen planus rather than to the polygonal umbilicated papulo-squamous lesion described by Erasmus Wilson. Goldberg records that the lichenoid papules are often present on the face especially the eyelids and ears, and he describes an appearance similar to erythema ab igne which may be noted on the eyelids when the eruption subsides. In 12 out of 60 cases studied the mucosae of the mouth lips penis or vulva were involved and in 3 out of 20 patients examined proctoscopically greyish white mucosal alteration was seen in the rectum on the columns of Morgagni the crypts not being involved. Gastroscopy failed to reveal lesions on the gastric mucosa. In a discussion of the aetiology Goldberg states that he has been unable to reproduce the lesions by the administration of atabrine mepacrine in the cases observed. All these [patients] were maintained on suppressive atabrine therapy while they were being treated and in no instance did any new lesions appear while under observation. It is true however that some of the hypertrophic lesions would weep but this could readily have been a reaction to local treatment. Several patients developed their first attacks of malaria or relapsed while in this hospital and were treated with intensive atabrine therapy but there was no aggravation of their skin lesions. One patient in particular with severe exfoliating dermatitis plus his lichenoid lesions has been observed for eight months during which time he has been receiving continuous suppressive atabrine therapy he has recovered except for scattered sepia brown pigmentation. Patch and intradermal tests with atabrine were done in a few of these patients and all were found to be negative. No passive transfer tests were made. Although atabrine may be a definite causal factor or an agent that prepares the soil more evidence will have to be uncovered before it can be pinned down as the exclusive and certain etiologic factor. Goldberg suggests that the neurophysiologic mechanism photosensitivity and infection appear to play roles as may as yet unknown geographic factors. He could not reach any definite conclusions as to a possible nutritional factor in producing this dermatosis.

In the treatment of the dermatitis phase the mildest salves and lotions could be used for the skin was easily irritated. Exfoliating cases were treated by the usual methods employed in any exfoliating dermatitis such as continuous wet dressing with 1/5000 potassium permanganate solution, corn starch and baking soda baths high caloric diets with added vitamin medication and the intramuscular administration of crude liver extracts in doses of 2 to 5 cc every day or on alternate days amino acids were given orally in large amounts. In the lichenoid phase small doses of oxophenarsine hydrochloride ['Alapharsen'] were given 0.02 gm bi weekly many of the patients responded well and the pruritus was often relieved before the third injection. The lesions of the mucosae responded equally with those on the skin. In no case were more than ten injections required to cause involution of the lesions. Several of the patients treated with Alapharsen developed fever up to 102°F about six hours after the first injection and when this happened administration of the drug was discontinued. It was believed that these cases had a subthreshold hepatitis which might have been caused by atabrine and activated by the arsenical injection, for their icteric indices were raised and some developed clinical jaundice. The reactions subsided in 48-72 hours.

[August, 1948]

(2) Factors which reduce the liability of a person to prickly heat are (a) age below thirty years, (b) previous sun tan (c) loose clothing, (d) open-air working and sleeping (e) low temperatures of place of work, and (f) perhaps the fact of belonging to blood group A (11)

(3) Factors having no effect on the incidence of prickly heat are (a) weight (b) sweat reaction (c) wearing of open-necked shirts, and (d) the effects of the sun on the subject's skin.

(4) Factors which from our investigations gave inconclusive results were (a) type of work, (b) humidity (c) brand of soap used.

These various factors do not seem to be a cause in themselves, but when present they affect a susceptible person as indicated. The disease seems to be more constitutional than to be due to any one factor in particular [Besides the observations summarized above the paper contains some clinical notes on the diagnosis and treatment of the conditions.]

TROPICAL ULCER.

SHEPHERD Margaret M. Metastatic Osteomyelitis Secondary to Tropical Ulcer. *Brit. J. Surgery* 1948 Apr v 33 No 132 352-7 5 figs.

In 11 out of 98 cases of tropical ulcer of the leg in young Gurkha soldiers, treated in hospital in Dehra Dun in the latter part of 1943 inflammatory lesions developed in various long bones the tibia was affected in six cases the femur in 3 the fibula in one, the radius in one and the clavicle was also involved in a patient in whom both tibiae were affected. The author has since seen two cases where the lesions were in the shaft of the humerus.

The first symptom was local pain and tenderness not usually severe and not usually complained of for several days after its onset in seven cases there was slight fever. The time of onset of this complication was usually several weeks—4 to 27—after the ulcer appeared and the ulcer was then clean and healing except in one case.

Radiologically the first change was a decalcification in the cortex of the diaphysis of a long bone. Then followed linear periosteal new bone deposit and a fluffy or woolly new bone having a broadly crenated outline. In some cases healing then occurred by deposition of calcium salts in the new bone. Very little resorption took place. In other cases changes indicative of osteomyelitis appeared before healing took place. The bone lesions are clearly shown in the radiographic illustrations.

Wassermann and Kahn tests were asked for and reports were received in nine cases but in one the blood was haemolyzed and in another it was contaminated the other seven were negative.

The bone lesions healed without special treatment (sulphathiazole was given in four cases) in from 5 to 27 weeks, average 12 weeks. In a footnote the author states that penicillin was tried in a few other similar cases with encouraging results.

[No bacteriological examinations appear to have been made except that in one case it is stated that blood culture was sterile.] J. F. CORSON.

MANOWA, S. L. A. An Excision Knife for Tropical Ulcers. *Brit. Med. J.* 1948 Apr 13 874 1 fig.

This knife is a bistoury curved on the flat. The author has found it useful for the excision of tropical ulcers.

MISCELLANEOUS DISEASES

CULLINAN E. R. Medical Disorders in East Africa: *Trans Roy Soc Trop Med & Hyg* 1946 Apr 1 39 No 5 353-63 1 map [11 refs] Discussion 368-72 [KEKWHICK A. WILCOCKS C. MANSON BAHR P. BIGGAM A. G. BOYD J. S. K. JAMES S. P. LOW G. C. McCULLAGH Mch. NAPIER, L. E. CULLINAN E. R. (in reply)]

This paper briefly surveys the medical disorders affecting British troops in the East Africa Command during the last 20 months of the recent war and makes a plea for future co-ordinated clinical research in East Africa.

The East Africa Command covered over a million square miles extending from 11°N to 25°S. It included Kenya Tanganyika, Northern Rhodesia, Nyasaland Italian and British Somaliland the reserved area of Abyssinia, Madagascar Mauritius the Seychelles and Zanzibar. The troops were fairly static at the time being in training for service in South East Asia and they comprised a cross-section of the fittest young adult native males of East Africa, and a representative sample of adult Europeans, all living under closely similar conditions.

The most prevalent medical causes of admission to Hospital, in both Europeans and non Europeans were malaria, dysentery and enteritis (including amoebiasis) and then upper respiratory infections. The incidence of other diseases however differed markedly in the two groups dengue and typhus being found mostly among Europeans while schistosomiasis relapsing fever leprosy and yaws were almost exclusively confined to the non Europeans. Digestive disorders were nearly five times skin diseases over three times and psychoneurosis over twice as frequent among the Europeans as among the Africans. The killing diseases of the Africans were tuberculosis meningitis and pneumonia, accounting respectively in 1944 for 16.0 per cent 12.1 per cent and 11.7 per cent. of all non-European deaths.

Nearly all the malaria in the mainland was due to *P. falciparum* but in a few districts especially in Somaliland Madagascar and Mauritius *P. vivax* was found while in Mauritius and rarely elsewhere *P. malariae* occurred. The malaria season varied greatly from region to region, but in the hyperendemic areas transmission was almost perennial. Immunity was labile depending upon the frequency of infection, and while the disease among non-immunes was of all grades of severity it was almost universally mild among the immune populations. It was therefore neither desirable nor necessary to give an immune African a full course of treatment for malaria.

Bacillary dysentery ran a mild course with few exceptions and the case-mortality was low: the deaths nearly all resulted from dehydration which seemed to occur more rapidly among the Africans. In the treatment of the disease sulphapyridine seemed as effective as sulphaguanidine.

The incidence of amoebiasis rose among Europeans as the years of war went by and in 1944 the number of European troops admitted to hospital with the disease corresponded to 20.27 per 1000. Treatment followed conventional lines with the usual rapid resolution of symptoms but in many of the European patients the disease relapsed, and those with frequent recurrences were generally sent home to the United Kingdom.

Skin diseases were relatively uncommon in African troops and among Europeans they were frequent only in humid stations. Tropical ulcers were very prevalent among the African troops in the earlier part of the war but towards the end of the war had almost completely disappeared.

Tropical Diseases Bulletin.

Psychoneurosis accounted for 17.59 per 1,000 of the admissions of the European troops to hospital, an incidence rate not unduly high in view of the prolonged absence from home, loneliness and lack of action. The majority of the European patients suffered from anxiety states whereas hysteria was the common condition among the Africans.

Relapsing fever common in many parts of East Africa, was largely confined to the native population. It appeared to be tick-borne except in Abyssinia, where the louse-borne type was also found. *Ornithodoros moubata* was the responsible tick vector. When the disease occurred in Europeans, cerebral complications appeared more frequently than among the Africans. Novarsensobillon seemed of little value in the treatment of the tick-borne fever and although penicillin had some effect the results were not sufficiently good to justify its general use.

The incidence of schistosomiasis among Europeans was very small. The few Africans admitted to hospital with the condition gave no real measure of the true incidence of the infestation among the natives, as an examination of the urines of 1,408 African troops all of whom were in active training and apparently fit revealed that 13.56 per cent were harbouring eggs of *S. haematobium*. The highest percentage of infected men came from Vavaland, where there is a large lake whose surrounding population is considered by local observers to be heavily infected from early childhood; the infection rate being estimated at 60 per cent of the inhabitants. Rectal schistosomiasis appeared to be relatively uncommon, and the incidence of *S. mansoni* throughout East Africa is not accurately known.

Acute pyogenic meningitis was much commoner in African than in European troops, and had a very severe clinical course. Usually the infection was meningococcal, but sometimes it was pneumococcal, no other local focus being found, and these pneumococcal infections were often particularly resistant to treatment both with sulphonamides and with penicillin.

Dengue was particularly common in Diego Suarez, at the northern extremity of Madagascar, and 94.2 per cent of all the cases in the Command occurred there during the first five months of 1944. Europeans were attacked over eight times as frequently as Africans. There were remarkable similarities between the clinical features of the disease and those of sandfly fever. There were a few small scattered outbreaks of idiopathic infective hepatitis the course of this disease was no more severe in Africans than in Europeans and the incidence was much less, while the opposite was true of post-erythema "laundice" Africans being more frequently and more severely affected than Europeans. Acute anterior poliomyelitis was rare excepting for a violent outbreak among the children in Mauritius early in 1945 when 1,000 cases occurred in a population of approximately 420,000. Leprosy was not uncommon among African troops, and was almost always of the neural type. Although malnutrition was frequent in recruits, indistinguishable from beriberi among some was, however, a sharp outbreak in Diego Suarez, whose diet for a time had consisted mainly of rice. This rice had been lightly milled, and in its uncooked state contained a theoretical sufficiency of thiamin. It was found, however, that while fresh lightly milled rice lost only 30 per cent and, moreover, this rice which was old and contaminated lost over 70 per cent and, moreover, it produced beriberi in pigeons.

Among young adult East African natives, pulmonary tuberculosis was generally acute and frequently ran a severe course with a high death rate. There is, however, a group with higher resistance which responds well to treatment but unfortunately most of the patients are unwilling to stay in

hospital for longer than three months. The African refuses to be separated from his family and one possible answer to the problem is the "settlement system" a tuberculosis centre on the lower slopes of Mt Kilimanjaro in Tanganyika is already doing excellent work in this direction.

The author stressed the need for co-ordinated epidemiological and clinical research in the Colonial Empire in the future not only for its potential scientific value but also for the interest it could give to large numbers of medical officers in remote stations. In June 1944 the D.D.M.S. inaugurated a Medical Investigation Committee for the purpose of encouraging facilitating and correlating research by medical officers in the East African Command. The response was immediate and enthusiastic, and within a year a considerable amount of valuable work had been done.

In the subsequent discussion several speakers enlarged on the desirability of further and wider research in the tropics. Brigadier J. S. H. BOYD mentioned that a Colonial Medical Research Committee had been formed to foster research on a wide basis with whole-time research workers. C. WILCOCKS thought that tuberculosis in the tropics demanded more attention and stressed the importance of poverty and ignorance in the aetiology of this and many other diseases in the tropics. Colonel S. P. JAMES was surprised to hear that nearly all the malaria had been due to *P. falciparum* and suggested that other species of parasite were not without importance in East Africa. Dr G. CARMICHAEL Low stated that the diseases reviewed were much as he had seen them in East Africa more than 40 years ago excepting that infection with *S. mansoni* was then common as were other helminthic infestations particularly filarial. Mr McKIM McCULLOCH remarked on the preponderance of appendicitis in Europeans as compared with Africans.

AVERY J. L. Parasitic Infections among Natives of the Samarai District, Papua, New Guinea. *J. Parasitology*, 1946 Feb v 32 No 1 25-9

Stained thick blood films and faecal specimens (one of each from each person) of natives in New Guinea were examined for parasites the faecal examination included a brine floatation method. One survey was made of a group of labourers chiefly to ascertain filarial periodicity while another survey was made of an entire native village adults and children [only three children aged 0-4 years had a blood examination in this village of 318 persons examined all three had malarial parasites].

The following incidence of infection was found in the village. *P. vivax* 105 *P. malariae* 50 *P. falciparum* 7 *Wuchereria bancrofti* 97 (taken at 9 p.m. to midnight). No mepracine was given to the natives except in the rare cases where seriously ill persons were taken to hospital. The microfilariae showed definite periodicity, increasing in the peripheral blood at night.

The incidence of *Entamoeba histolytica* was low—3 out of 53 labourers and 3 out of 300 villagers. Other protozoa found were *E. coli*, *Endolimax nana*, *Giardia lamblia* [*G. intestinalis*] and *Trichomonas hominis* and all had a low incidence (1 or 2 per cent.).

Two species of intestinal helminths were found. *Trichuris trichiura* (1 out of 53 labourers and 128 out of 300 villagers) and hookworms (40 out of 53 labourers and 263 out of 300 villagers) the species of hookworm could not be determined.

Anopheles punctulatus punctulatus was very abundant other mosquitoes present were *A. p. moluccensis* [*A. p. farauti*] *Aedes scutellaris* and *Aedes kochi*.

LINDSAY S F Fatigue Syndromes in West Africa. *Brit Med J* 1946
May 18 753-60

A number of men of the British Army in West Africa Command who showed signs of physical and mental fatigue were studied from the point of the relation of climate to ill-health in the moist tropics.

The cases 88 in number were classified into five groups, the first consisting of 64 with fatigue as the main symptom. This group was sub-divided into (1) those with signs of simple physical and mental fatigue (2) those with exaggerated or abnormal psychological reactions, (3) those with toxic illness. The remaining groups consisted of those with psychoneurosis, depressive states, psychosis and a post-concussion syndrome complicated by fatigue symptoms.

Investigation showed that the West African climate was only partly the cause of the breakdown. Everyone living in this climate is liable to experience some degree of languor but most people learn to adapt themselves to the limitations thus put upon their activities. The part played by the climate is to aggravate any pre-existing weakness physical or psychological. Even the problem of adjusting themselves to the ways of the African native is too difficult for some people and they react with irritability and frustration, leading to tiredness and depression.

The total personality with its physical, intellectual, emotional, social and moral components must be considered when studying reactions to climatic stress.

Some detailed case histories are given.

[An interesting study of fatigue problems in an unusual setting providing some further confirmation of previous findings in various industrial environments particularly noticeable owing to the exaggerated conditions resulting from the war]

May Smith

DOWLING P G Epidemic Polyarthrits. *Med J Australia* 1946 Feb 23
v 1 No 8, 245-6

This is a description of an outbreak of a short, mild fever accompanied by polyarthrits, which occurred among Australian troops in North Queensland during February, March and April, 1945. The disease was obviously the same as the "acute polyarthrits" described by HALLIDAY and HORAN as occurring in the Northern Territory of Australia [see this *Bulletin* 1944 v 41 279]. An outbreak in Queensland in 1944 was described by SIMON.

In the present outbreak 94 cases occurred among various units in a camp seven miles in length. In a unit at one end of the camp there were 47 cases. In four units a short distance away there were 39 cases. The remaining eight cases were from units in other parts of the camp.

Every patient suffered from pain and stiffness of several joints especially those of the hands and feet. Swelling was observed in about three-fourths of the cases, and there was effusion into one knee-joint in three cases.

The swelling which was periarthritic in most instances, persisted for four to seven days. The pain usually disappeared a few days later but in three cases it lasted for three months. Some of the patients had no fever but most of them had a slight rise of temperature to 99-101°F for two to five days. One patient exceptionally had a temperature of 103°F. The onset was gradual. In 60 per cent. of the cases there was a papular or macular rash, which appeared on the first to the seventh day and lasted for two to seven days. It was usually first seen on the trunk, then on the limbs. Sometimes it was generalized.

In four cases small vesicles developed on the papules within twenty-four hours of the appearance of the rash, and these patients were first thought to

be suffering from varicella. Redness of the fauces was seen in 12 patients. One or more groups of lymph glands were swollen and tender in about half of the cases.

The leucocyte picture was normal. Blood cultures were sterile. The outbreak, like the others recorded occurred in the wet season it began two weeks after heavy falls of rain and was associated with a great increase in the prevalence of mosquitoes. Two weeks after the commencement of the outbreak and one week after starting mosquito-control measures new admissions rapidly diminished in numbers.

Culex fatigans was the only mosquito of which adults were found in all the three camps in which a survey was made. It was present in large numbers. Larval *Aedes notoscriptus* and *Aedes alboannulatus* were found. Adult *Anopheles annulipes* were found in two of the camps and adult *Culex lutzii* in one. Other possible insect vectors were considered, but none was prevalent in the area at the time. There was no evidence of spread by contact, and the author concludes that the possibility that this disease is a mosquito-borne infection requires investigation.

He suggests that the name epidemic polyarthrititis is suitable for the condition, because it avoids confusion with other serious forms of polyarthrititis.

[The name proposed by the author for this problem fever seems to be preferable to acute polyarthrititis. As opportunities for investigation into the cause may not recur the disease will perhaps remain one of the minor unsolved mysteries of the war. The name polyarthritic febricula would possibly have been more descriptive than the others suggested.] *John W. D. Meigs.*

RUDRA M. N. & BHATTACHARYA, K. P. Serum Phosphatase in Lathyrism. *Lancet* 1946 May 11 688.

Lathyrism is the result of degeneration of part of the nervous system and there is an intimate relationship between vitamin B₁ and the nervous system. The authors therefore studied the nutrition of lathyrism patients from this vitamin aspect but found that the vitamin was present in normal limits in the blood and urine. They next estimated the serum-phosphatase in normal subjects and compared it with that of sufferers from lathyrism. In 12 of the former it ranged between 0.8 and 5.7 units with a mean of 2.38; among 10 lathyrism cases it ranged between 18.7 and 56.5 with a mean of 38.7 units. It is suggested that this increase may destroy the circulating co-carboxylase so that the patient is functionally though not actually deficient in vitamin B₁ with consequent affection of the nervous system.

This is put forward as a hypothesis but the hiatuses to be filled are great. The authors can offer no explanation of the increase of serum phosphatase in lathyrism and themselves make the suggestion that it may not be the cause but the effect of lathyrism for usually the serum phosphatase level is a measure of the severity of the disease. [A stimulating piece of work.]

GENERAL PROTOZOOLOGY

LEHMANN, G. D. & PRENDIVILLE, J. T. Occurrence of a Flagellate in the Sputum of a Case of Bronchiectasis. *Brit. Med. J.* 1946 Feb 2, 158-60. 2 diagrams. [17 refs.]

The paper describes a case of bronchiectasis in which flagellates in diminishing numbers were present in the sputum on four successive days. The disappearance of the flagellate coincided with the relief of symptoms under sulpyridine treatment which however did not prevent a fatal issue. The

Tropical Diseases Bulletin

flagellate 10-15 μ in length by 5-7 μ in breadth was actively motile its movements being the result of the action of two equal anterior flagella and of amoeboid changes in shape. It was generally pear shaped, the posterior broader end frequently being elongated to form a caudal process. In some respects the organism resembles the flagellate stage of *Dimastigamoeba gruberi* but this organism does not develop an elongated caudal process in its flagellate stage which is merely transitory the stable form being an amoeba. It is suggested that an amoeboid phase might have been present in the lung cavities and that the flagellate phase occurred only when dilution of the material with bronchial secretion and saliva took place. It seems not unlikely that the organism is an altered trichomonas a possibility considered by the authors. No pathological significance is attributed to the presence of the flagellate in the material coughed up from the lung. The paper is illustrated by a number of line drawings.

CHIFFAU C & CHIFFAUX MATHIS Jeanne Le *Trichomonas vaginalis* chez la femme noire togolaise. Etude épidémiologique clinique pathogénique et thérapeutique. *T vaginalis* in Togoland Women. *Méd Trop* Marseilles. 1944 Sept-Oct.-Nov.-Dec. 4 No 4 289-300 [21 refs.]

The authors have examined 151 native women of Togoland, aged 18 to 45 for evidence of *Trichomonas vaginalis* infection which might account for the symptoms of pain and vaginitis of which they complained. Of these women 45 were found infected giving an incidence of 29.8 per cent. which is nearly double the infection rate encountered among white women making similar complaints examined in Marseilles. The authors think that the higher incidence amongst the black women may be due to some particular racial susceptibility. They admit that *T vaginalis* is usually present as a saprophytic organism only but that occasionally it may take on pathogenic properties. The paper discusses many aspects of the subject the authors basing their remarks on personal observations and a general review of the literature.

GENERAL ENTOMOLOGY

JUNTER G W WELLS, T H & JAMES, W G Jr An Outline for teaching Mosquito Stomach and Salivary Gland Dissection. *Amer J Trop Med* 1946 Mar. 26 No 2 221-8 13 figs. [17 refs.]

The technique of mosquito dissection described in this paper is not new neither is the method of teaching it but after trying many others they were adopted by the American Army Medical School as being the most satisfactory for the training of large groups of individuals who had no previous knowledge of entomology.

The course consists of one lecture on mosquito anatomy followed by two practical periods of two hours each. Uninfected mosquitoes are dissected during the first practical period and infected ones during the second. A full description of the technique is given, oöcysts and sporozoites are described and illustrated and there is a list of the necessary equipment. A useful paper for the beginner.

SAUTET J & AUDIERET J Etudes biologiques et morphologiques sur certaines larves de moustiques en vue d'applications pratiques pour leur destruction. (Première partie.) [Biological and Morphological Studies on Mosquito Larvae.] *Bull Soc Path Exot.* 1946 v. 39 Nos. 1/2 43-61 13 figs

The work described in this paper was done at the Hygiene Research Centre, Marseilles where the mosquitoes *Theobaldia longiareolata* *Culex pipiens* and *Culex hortensis* are being studied.

An account of the structure and function of the terminal respiratory apparatus of the larva of *Culex pipiens* is followed by a description of some experiments on larvae imprisoned under water. Survival times of such larvae were recorded at different instars in standing and running water under winter spring and summer conditions in the presence and absence of aquatic vegetation and food. Usually six to eight larvae were put into two litres of water.

Some of the results are tabulated and briefly discussed, and in general tend to show that submerged larvae are able to withstand such conditions for longer periods in water which is cold and running than in warm still water the presence of food and aquatic vegetation helps to prolong their resistance. First and second stage larvae are shown to be more resistant to mechanical suffocation than are the older larvae.

The paper is to be continued.

SIMMONS S W & Staff Techniques and Apparatus used in Experimental Studies on DDT as an Insecticide for Mosquitoes. *Supplement No 189 to Pub Health Rep* Wash. 1945 3-20 11 figs

Important outstanding problems in mosquito control by DDT are the number of mosquitoes leaving treated houses before having received a lethal dose of insecticide and the relation between lethal effect and dosage and interval since application on different wall surfaces. The authors describe techniques used in investigating these subjects. This review merely indicates the general scope of their equipment which is described in the original in sufficient detail to make exact reproduction possible.

Mortality amongst mosquitoes leaving treated houses is studied by means of a window trap placed over windows on northern or western aspects of the house. Several types have been tried in the most successful type some windows and doors were left open to allow free ingress of mosquitoes and one or two windows are closed by means of a framework in the general shape of a window hinged at the bottom and opening outwards to an angle of about 15 degrees from the vertical. The upper horizontal surface of this frame has an opening over which a cage is placed and left for 24 hours this is subsequently removed and used as a holding cage in which mosquitoes can be observed without further handling. A bigger catch is obtained by this means than by others which have controlled inlets as well as outlets and specimens captured are considered to be a representative sample of those leaving the room by all apertures.

Testing of toxicity of surfaces may be needed under two sets of conditions (1) in rooms which have been treated and occupied in a normal manner and (2) in the laboratory where it is desired to remove all disturbing factors such as mechanical handling so that the treated surface can be left under standardized conditions. For the first of these the authors use a holding cage in the shape of a truncated cone and made of plastic a plunger cage resembling an enlarged syringe by means of which mosquitoes can be transferred with the minimum of trauma and glass Petri dishes held in a special framework attached to the wall

by means of brackets 15 to 20 mosquitoes being held between the Petri dish and the wall and preferring to alight on the latter as a result of their difficulty of holding on to the glass. After exposure to the treated surface, mosquitoes are liberated into holding cages for observation.

For laboratory tests the authors use a darkened holding cage a glass lantern chimney which mosquitoes are persuaded to enter by light attraction, an air blast mechanism by which they are transferred without damage to the experimental cage arranged to accommodate panels of wood or other material which have been treated under standardized conditions. At the end of the exposure time mosquitoes are transferred to observation cages.

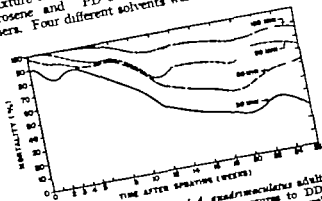

[These last two techniques provide a rapid method of accurately estimating the toxicity of surfaces to mosquitoes artificially held in contact with them which should yield results which can safely be used in statistical comparisons. The same degree of reliability could not be attributed to the first technique for the estimation of mortality amongst mosquitoes entering treated rooms.]

G Macdonald.

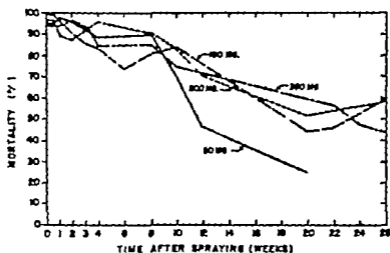

FAY R. W. SIMMONS S. W. & CLAPP J. M. Laboratory Investigations on the Toxicity of DDT Residues to Adults of *Anopheles quadrimaculatus* Supplement No 186 to Pub Health Rep Wash 1945 21-34 11 figs.

Using the technique described by SIMMONS and Staff (see above) *Anopheles quadrimaculatus* mosquitoes of both sexes as test insects doses of DDT of 50 100 200 and 300 mgm. per sq. ft. exposure periods varying from 35 to 120 minutes and periods of observation up to 28 weeks the authors show that mortality varies directly with exposure time but not materially with the dose of DDT applied, provided it is 100 mgm. per sq. ft. or more. In fresh films the effect of variations in the period of exposure of mosquitoes is relatively slight but in older films it increases until in films 28 weeks old there is a mortality of 31.2 per cent. amongst mosquitoes held in contact with them for 35 minutes and of 89.1 per cent. amongst those in contact for 120 minutes. These results are illustrated in the two graphs reproduced below.

The residual activity of DDT deposited from different solvents again observed over a period of 28 weeks showed moderate differences. The toxicity of a film deposited from an orthodichlorobenzene mixture wore off rapidly and a Drefit Talc mixture showed poor adhesion and had to be abandoned. Gas condensate kerosene and PD 544 C and PD 544 B appeared to be better than others. Four different solvents were also used for the preparation

Average 48-hour mortalities of 4 *quadrimaculatus* adults after 35-, 60-, 90- and 120-minute exposures to DDT residues of 50 to 300 mg per square foot from 1 to 28 weeks after application.

Per cent. mortalities of *A. quadrimaculatus* adults after 80-minute exposures to 50 100 200 and 300 mg DDT per square foot residue at 1 to 28 weeks after application.

[Reproduced from Supplement No 186 to the Public Health Reports]

of films exposed to weathering and no material difference was found between them. In each case direct sunlight produced a slow steady deterioration in effect whilst rain produced a rapid deterioration over the first four weeks after which no further change occurred up to eight weeks.

[The observation that the dose of DDT does not materially affect mortality rates conflicts with the findings of other authors notably METCALF *et al* (this Bulletin 1946 v. 43 102). The range of doses in the two cases was very different 50 to 300 mgm. in the present series 40 to 1 000 in the previous series but they do seem to display some material difference. The exact techniques used in the present series must be considered as making their results very reliable.]

TARZWEIL C. M. & STIERLI H. The Evaluation of DDT Residual Sprays for the Control of Anopheline Mosquitoes in Dwellings. Supplement No 186 to Pub Health Rep. Wash. 1945 35-48 5 figs.

The net mortality of mosquitoes naturally entering unoccupied rooms was studied by the method elaborated by SIMMONS and STAFF [see above] in which a proportion of those attempting to leave are captured and held under observation for 24 or 48 hours. The majority of the mosquitoes were *Anopheles quadrimaculatus* and about 77 per cent of the dead recovered were males. This high proportion is attributed to the fact that the experiment was carried out close to breeding places and possibly to a higher resistance of females than of males to DDT. The mortality figures obtained in treated houses were checked by the findings in untreated control houses and corrected by a formula which took account of the numbers dying naturally in the untreated places. The results in two representative vacant buildings are shown graphically in Figure 1.

When a similar technique was tried in occupied houses the net kill was much lower. For periods of two to six weeks after treatment mortalities of 39 per cent. at 24 hours and 54 per cent. at 48 hours were recorded the reduction being attributed to the presence of furnishings and objects hung on the walls which greatly increased the amount of untreated surface on which mosquitoes might alight. There were indications that doses of 200 to 400 mgm DDT per sq ft were more effective than doses of 100 mgm.

Tropical Diseases Bulletin.

Effective 24 and 48-hour mortalities taken in window-traps of unoccupied houses A and B, treated with 200 mg of DDT per square foot. Each point is a summation of 7 daily collections.

(Reproduced from Supplement No. 188 to the Public Health Reports.)

In addition to these trials on mosquitoes naturally entering rooms others were made in which captured or insectary-bred *4. quadrimaculatus* were liberated into rooms all openings from which could be occluded by traps, and which had been treated with 100 200 400 and 800 mgm. DDT per sq. ft. Five to 35 minutes after release the mosquitoes became irritated and began to move about some towards the light simultaneously suffering from tremors and incoordinated flight. The number moving towards the light gradually increased till the numbers resting on the untreated screen of the window trap reached a maximum between 30 and 60 minutes after release. Many of those moving towards the light had, however, already received a dose which proved fatal before they actually entered the window traps, and of those which entered them practically all died within 24 hours. Contrasting recently-applied and ageing films it was found that with the latter the time required for knockdown was increased but that otherwise the results were substantially the same as with the former. Rate of knockdown was also affected by dosage 50 per cent morbidity being reached at 93 67 and 60 minutes after liberation into rooms treated with 100 200 and 800 mgm per sq. ft.

In some of the experiments the temperature was recorded, and it is stated that temperature greatly influenced the rate of knockdown the higher the temperature the more rapid effect of the DDT. In the opinion of the reviewer the data presented are inadequate to substantiate this statement.

STIERLI H SIMON W TAREWELL C M Operational Procedures and Equipment used in the Practical Application of DDT as a Residual House Spray Supplement No. 183 to Pub Health Rep Wash. 1945 49-65 5 figs

Kerosene solutions of DDT were found to have practical disadvantages which made the use of emulsions preferable. A formula found useful for large scale work was —DDT 3 lb xylene 3 quarts and Triton X 100 (a proprietary emulsifier) 8 fluid ounces. One gallon of a concentrate made to this formula, mixed with 8 gallons of water makes a nominal 5 per cent. spray of which 1 gallon to 948 sq. ft. gives a DDT dosage of 200 mgm per sq. ft. In cold weather DDT is not so soluble and the concentrate is therefore weaker

for winter work 2 lb of DDT were dissolved in 1 gallon of xylene with 0.2 quarts of Triton X 100 to form a concentrate of which 1 gallon mixed with 3 gallons of water gives a 5 per cent. emulsion

For small scale projects mixing was carried out in a 55-gallon wooden barrel mounted on rockers like those of a rocking chair and fitted with handles by which it could be shaken by means of this 50 gallons of concentrate could be mixed every hour For work on a larger scale a power mixer was devised and is described in detail.

Both hand-operated and power sprayers were used. The hand sprayer was of the pneumatic type in which before working, an air pressure of 50 lb per sq in is developed by means of a hand pump A nozzle giving a fan shaped spray at a delivery of 0.2 gallon per minute was used and was held 24 to 30 inches from the wall. The power sprayer when adjusted to 60 lb per sq in pressure delivered 0.24 gallon per minute with which delivery 230 sq ft. could be treated every minute Useful data are given on this and accessory equipment needed in practical work on the training of workers the preparation of houses and the technique of spraying

One overseer and two labourers using power equipment mounted on a truck could spray 40 houses per day each averaging 1 750 sq ft. of surface The cost of treating 1 000 sq ft of surface was —materials 35 cents labour 24 cents fuel, lubricants maintenance and repair (by inference) 10 cents total, exclusive of overhead costs 69 cents.

Piston-type atomizing hand sprays were found to be useless and a power operated paint sprayer was unsatisfactory It was estimated that in urban areas a three man crew with a power sprayer was equal to or better than a five-man crew with hand sprayers and that the cost of their equipment was 400 dollars as against 200 dollars for the five men with hand sprayers

ARNOLD E. H. FERGUSON, F. F. & UPHOLT W. M. *The Experimental Use of DDT Sprays as Mosquito Larvicides. Supplement No 188 to Pub Health Rep Wash. 1945 66-79 8 figs*

Emulsions of DDT made from concentrates consisting of 5 per cent DDT in oil with various proprietary emulsifier spreaders diluted [? 30 times] with water gave 98 to 99 per cent kill of anopheline and culicine larvae under a variety of conditions when the dose of DDT applied was 0.1 lb per acre There was however a disappointing lack of spread of the DDT from the point of application and experiments showed that the lethal effect was limited to the distribution of the solvent consequently emulsions were considered unsatisfactory for anti larval work. Surface films of non-emulsified oil solutions were superior and a 1.25 per cent. solution of DDT in No. 2 fuel oil with 0.5 per cent B 1956 (a proprietary emulsifier-spreader) was considered satisfactory

A residual larvicidal effect was not obtained with small doses 0.5 lb per acre gave control for only an additional week and had the undesirable effect of killing fish. In one case where 1.7 lb per acre was applied to an area which had previously received 0.9 lb per acre in divided doses the water remained devoid of all animal life except plankton for over a month and samples of the water showed definite toxicity to insectary-reared larvae.

Suspensions of DDT made by adding it to alcohol with a dispersing agent and later diluting the mixture with water had properties similar to those of emulsions. DDT dissolved in heavier than water oil, as a bottom application was inferior to any of the surface applications as a larvicide and was more lethal to other aquatic life

ARNOLD E. H. FERGUSON, F. F. & UPHOLT, W. M. The Experimental Use of DDT Sprays as Mosquito Larvicides. *Health Rep Wash.* 1945 68-79 8 figs. *Supplement No 186 to Pub*

Emulsions of DDT made from concentrates consisting of 5 per cent DDT in oil with various proprietary emulsifier spreaders diluted [? 30 times] with water gave 98 to 99 per cent kill of anopheline and culicine larvae under a variety of conditions when the dose of DDT applied was 0.1 lb. per acre. There was however a disappointing lack of spread of the DDT from the point of application and experiments showed that the lethal effect was limited to the distribution of the solvent consequently emulsions were considered unsatisfactory for anti larval work. Surface films of non-emulsified oil solutions were superior and a 1.25 per cent. solution of DDT in No 2 fuel oil with 0.5 per cent. B 1956 (a proprietary emulsifier spreader) was considered satisfactory.

A residual larvicidal effect was not obtained with small doses 0.5 lb per acre gave control for only an additional week and had the undesirable effect of killing fish. In one case where 1.7 lb per acre was applied to an area which had previously received 0.9 lb per acre in divided doses the water remained devoid of all animal life except plankton for over a month and samples of the water showed definite toxicity to insectary reared larvae.

Suspensions of DDT made by adding it to alcohol with a dispersing agent and later diluting the mixture with water had properties similar to those of emulsions. DDT dissolved in heavier than water oil as a bottom application was inferior to any of the surface applications as a larvicide and was more lethal to other aquatic life.

An enquiry into the reason for the absence of residual larvicidal action showed that the bottom mud complex in some way binds the DDT in a form that is not available to larvae though colorimetric estimation suggests that it is chemically unchanged. 100 gm. of mud will absorb as much as 4 mgm. of DDT in this way and the effect is not dependent on bacterial action.

An experiment with minimal doses of DDT in fuel oil and in gas condensate liquor both of which produce surface films showed that the latter was considerably the better vehicle though with normal doses of 0.1 lb. per acre the two were equal in value.

G Macdonald.

LACKEY J B & STEINKLE Mary L. Effects of DDT upon some Aquatic Organisms, other than Insect Larvae. Supplement No 186 to Pub Health Rep Wash. 1945 80-89

DDT applied in a variety of vehicles with different emulsifiers has no effect on macroscopic vegetation though it might be inactivated by the zoogeal coverings of plant stems. Doses of 1.0 part per million are poisonous to *Gambusia affinis* which, however avoids the treated area if there is a safe retreat and thus may escape destruction. Water treated with this amount of DDT becomes non-toxic within 5 days of treatment. Tadpoles and crayfish are killed by similar doses though with the latter the results are inconsistent. Aquatic worms and rotifers are not affected by doses of 0.25 to 1.0 part per million. *Daphnia* and perhaps other crustacea are killed in the laboratory by doses of 0.1 part per million though *Clamvolutacea* resist 20.0 parts per million. The evidence indicates that DDT as normally used is harmless to much, if not all of the protozoal and algal population.

The authors suggest that the use of DDT might break the biological chain between protozoa and fish by eliminating aquatic insect larvae small crustaceae crayfish and fresh water shrimps and once this chain is broken it may take a long time to re-establish a normal fish population. They conclude that a detailed study of the subject should be made.

UPHOLT W M GAINES T B SIMMONS S W & ARKOLD E H. The Experimental Use of DDT in the Control of the Yellow Fever Mosquito *Aedes aegypti* (L). Supplement No 186 to Pub Health Rep Wash. 1945 90-96.

The fact that *Aedes aegypti* breeds in water containers which do not contain mud (which inactivates DDT) or fish (which might be killed by large doses) might make it possible to achieve residual larvicidal action against this mosquito. Experiment shows this to be possible and that the efficiency of anti-*Aedes* campaigns can therefore be increased. A great variety of miscellaneous water containers were treated with DDT emulsion concentrates at doses of 1 part DDT per million and over. In all cases residual action was obtained and in some for periods as long as six months. In many cases the containers had been emptied and refilled in the meantime and it seemed that the container itself remained toxic despite the water changes once it had been treated. This conclusion, arrived at in the field, was tested and verified in the laboratory where it was shown that articles sprayed with DDT emulsion and subsequently repeatedly filled and emptied, remained toxic over several months. Similar results were secured when DDT was applied as a 20 per cent. mixture with a wettable powder.

Larvae of *Aedes aegypti* become morbid as a result of exposure to DDT much more quickly than larvae of *Anopheles quadrimaculatus* though they usually survive for a longer period of time. When final mortality is considered there is little difference in the resistance of the two mosquitoes.

The presence of DDT in water or on damp surfaces does not deter mosquitoes from ovipositing. *Aedes aegypti* prefers to oviposit on moist surfaces rather than on water but eggs laid on surfaces treated with DDT hatch normally, most of the larvae however die within three days of hatching. Pupae are not affected by DDT though the vehicle in which it is applied may be lethal to them.

LINDQUIST, A. W. MADDEN, A. H. HUSMAN, C. N. & TRAVIS, B. V. DDT dispersed from Airplanes for Control of Adult Mosquitoes. *J. Econom. Entom.* 1945 Oct. v. 38 No 5 541-4 2 figs.

This report describes the results of spraying 5 per cent. solutions and emulsions of DDT from a Piper Cub airplane over ground covered with dense mangrove and bush of varying density for the destruction of adult *Aedes taeniorhynchus* which were present in great numbers. The results were assessed by estimating the numbers of mosquitoes attempting to bite test subjects in the areas before and after spraying and in untreated neighbouring areas.

Twelve tests on plots ranging from 8 to 30 acres each with 2 quarts of 5 per cent DDT per acre showed very similar results with emulsions and solutions. After spraying observations were made at 1, 4, 7, 24 and in a couple of cases at 48 hours. At the first observation there was a reduction of about 60 per cent. and this increased at each subsequent count till at 24 hours the reduction varied from 69 to 99.5 per cent and averaged 88 per cent. This gradual change coupled with the dense vegetation which made direct contact of the falling spray with many mosquitoes unlikely led the authors to believe that lethal action was largely the result of residual films on vegetation and not an immediate effect of the spray.

Dusts containing DDT in similar quantities and scattered from aircraft caused no reduction observable at 24 hours. Two trials with smokes generated by injecting DDT solution into the exhaust pipe gave different results. In one no control was secured, in the other a 98 per cent reduction was recorded at 24 hours. The authors believe that in this last case there had been poor smoke generation and most of the DDT had been liberated in a spray.

LINDQUIST, A. & McDUFFIE, W. C. DDT-Oil Sprays applied from an Airplane to control *Anopheles* and *Mansonia* Mosquitoes. *J. Econom. Entom.* 1945 Oct. v. 38 No 5 545-8.

In two tests carried out in the Panama Canal Zone sprays containing 10 per cent DDT in a mixture of cyclohexanone and oil were distributed from aircraft at doses of 2 quarts per acre over mosquito-infested forest of moderate density. Before and after spraying estimates were made of the numbers of mosquitoes *Mansonia* spp and *Anopheles* spp mainly *A. albimanus* attempting to bite test subjects. In each of the two areas there were six observation stations at each of which several counts were made. The averages of the results are shown below —

[August 1948]

First Test			Second Test	
Date	Mosquitoes per man per minute		Date	Mosquitoes per man per minute
	Mosquitos	Anopheles		Mosquitos
Before spraying			Before spraying	
13 4	24	1	18 4	4 7
14 4	21	1 3	19 4	4
			After spraying	
After spraying			20 4	0 19
15 4	0 18	0	21 4	0 58
16 4	0 48	0		
18 4	0 64	0 0 5		0 37

All larvae in a shallow lagoon, several acres in extent were destroyed in the first test, and no fresh breeding was recorded for a week G Macdonald

KIRK R & LEWIS D J Taxonomy of the Ethiopian Sandflies (Phlebotomus)
I. Classification and Synonymy Ann Trop Med & Parasit. 1948
Apr. v 40 No. 1 34-51 29 refs

The literature on Phlebotomus is scattered, and the insects themselves are difficult to distinguish owing to their small size and to the fact that, recently, workers have used internal characters for the differentiation of species. Knowledge of the African species has tended to advance less rapidly than of those of the Oriental and Mediterranean regions. Kirk and Lewis's series of papers will therefore be very welcome.

The authors classify the Ethiopian sandflies into three sub-genera Phlebotomus (restricted), Simulium, and Phlebotomus. The rest consists of a series of notes on the individual species giving their synonymy, their broad distribution and some comments on the species themselves. No keys or other means for actual identification are provided, and consequently, pending the appearance of keys in further parts of the series the present paper is not to be expected to provide a means for identification though it does provide any worker on the sandflies with a mine of information that may save him from endless burrowing in the literature of the genus.

PALMER, E. D. Intestinal Cantharidiasis due to Tenebrio molitor. J Parasitology 1948 Feb. v 32 No 1 54-5.
An infant whose food from the age of three weeks contained cereals began at the age of 4 months to vomit frequently between meals and when 5 months

old began to pass by the rectum larvae identified as *Tenebrio molitor* (the meal worm) the adult beetles were later found in the infant's precooked cereal food. Several of these larvae were passed during 3 months six were recovered and two of them lived for at least two weeks in a dry air tight jar. The child continued to gain weight but fed poorly vomited frequently and had long spells of crying. There was no diarrhoea or melaena and no larvae were vomited. Purges and enemas had no apparent effect and larvae were still being passed 3 months after the first [see also this *Bulletin* 1921 v 17 125 1933 v 30 317] J F Corson

MICHENER C D A Method of rearing Chigger Mites (*Acarina Trombiculinae*)
Amer J Trop Med 1946 Mar v 26 No 2 251-6 4 figs

As yet no really satisfactory method of rearing Trombiculid mites in the laboratory has been devised. It would be valuable to have some such technique for studies of the rickettsiae of scrub typhus carried by Trombiculid mites. This paper describes various techniques which may be useful to workers on this subject but which have produced no notable advances in handling the mites. To obtain fully fed larvae an infested chicken or pigeon is placed in a cage above a dish of water and the parasites which drop off after engorging are easily recovered from the surface of the liquid. They are removed from the surface on small pieces of newspaper by this means they can easily be handled without damage. These larvae are then kept in a glass jar with a thin layer of plaster of paris covering its walls. This gives a suitable humidity without the production of moulds and enables a high proportion of nymphs to be obtained.

The nymphs are kept in a similar jar in a mixture of five parts of sterilized soil with one part of chicken manure. This medium is exposed to the air so that the top surface becomes dry and the mites are discouraged from migrating from it. In about three weeks (at approximately 80 F) some adults were produced, but a fairly high mortality was found and few laboratory produced adults ever laid eggs.

Adult mites caught in the soil in nature readily laid eggs under similar conditions and if the soil-manure mixture was kept firmly pressed the eggs were restricted to the surface layer and were easily found. They hatched to give larvae which could be fed on chickens. Small pieces of wet paper were used to transfer the larvae to the host and when these dried the mites walked on to the skin and attached themselves.

Although some success has been achieved here in breeding the mites it is clear that many improvements of technique will be required before sufficient of these Trombiculid mites can be obtained for laboratory experiments.

WILLIAMS R W A Contribution to our Knowledge of the Bionomics of the Common North American Chigger *Entrombicula alfreddugesi* (Oudemans) with a Description of a Rapid Collecting Method. *Amer J Trop Med* 1946 Mar v 26 No 2 243-50 3 figs [11 refs.] Kenneth Mellanby

The mite *Entrombicula alfreddugesi* is a common cause of scrub itch in the southern part of the United States. The method described here for collecting large numbers of mites allows as many as 500 larvae to be obtained in one hour. About six white saucers are placed on the ground in likely areas and the reddish coloured larvae are easily visible on the surface. They can be collected without damage by a simple aspirator similar to that used for catching mosquitoes fleas etc.

BOOK REVIEW

ADRIENS L. [Docteur en Sciences chimiques etc.]. Contribution à l'étude de la toxicité du manioc au Congo Belge. [Study of the Toxicity of Manioc in the Belgian Congo] Institut Royal Colonial Belge. Section des Sciences Naturelles et Médicales Mémoires (Collection in -8°) 1946 v 13 No 4 140 pp. 2 diagrams.

This is an account of work carried out by the Chief of the Laboratory for Chemical Research in the Belgian Congo—it obtained Honourable Mention at the Annual Congress of the Belgian Royal Colonial Institute in 1940. The long delay in publication is no doubt due to the war.

Manioc *Morinda utilis* Bitter Cassava is used for its flour for preparing tapioca its starch, cassava cakes etc and it contains a cyanogenetic principle in common with *Phaseolus lunatus* and *Linum usitatissimum* whereby on addition of water for example hydrocyanic acid is set free and may cause fatal poisoning.

The author has undertaken an intensive study to determine the nature of the poison the factors which participate in the elaboration of the cyanogenetic heterosides and how these may be destroyed or got rid of. He describes in detail the various ways in which the preparations of manioc are obtained, by maceration, by boiling or by roasting—how by repeated washing by removal of the outer layers or otherwise the poisonous tuber can be made innocuous. These facts are already common knowledge and the author after these preliminaries goes on to describe his personal researches which have been directed to determining, first the action of the emulsion of manioc on the amygdaloid, Congo manioc containing an emulsion which breaks down the amygdaloid liberating the hydrocyanic acid. Secondly the action of this emulsion on dimethylcyanhydrin, the synthetic aglycone of the heteroside of manioc thirdly the action of emulsion on the synthesis of aldehydes ketones and glucides with HCN using for this purpose benzoe aldehyde acetone glucose and certain glucidic products. Lastly the action of decomposition products of aglycone on certain glucides. All these are considered and recorded with a wealth of detail described in the letterpress and illustrated with a number of protocols.

The point of chief practical importance is a commercial one. Cassava or manioc is an excellent food but unfortunately in its native state it is toxic. To remove the poison at all events to reduce it to the smallest possible amount careful preparation is necessary and if in spite of all care small quantities of the poison still remain the addition of "proportionally insignificant amounts of glucose will dispose of the danger. The method consists essentially in dividing the tuber (sometimes decorticated, but not always) into cubes or small pieces (*cosettes*) exposing them to the sun the whole day and at dusk placing them where they are protected from the moisture of the night air next day the pieces are dried in a hot-air stove at a temperature of 35–40°C not higher than the latter otherwise the product becomes brown and scorched-looking. If they are to be consumed at once they should be cut small and left in a large quantity of water to soak this water must be thrown away. For sale the agents need the *cosettes* to be dry really free from all moisture to this end the drying should be rapid and the product protected from dew or the moisture of the night air otherwise the drying process must be repeated moreover moisture will favour growth of mould and bacteria in transit.

This work will have much interest for the agricultural research chemist and, possibly for the toxicologist but makes no practical appeal to medical men.

BLACKWATER FEVER—MODERN THEORIES

A CRITICAL REVIEW

By B G MAEGRAITH B.Sc. D.Phil. M.B. B.S.

*Alfred Jones Professor of Tropical Medicine Liverpool School
of Tropical Medicine (University of Liverpool)*

Aetiology

Blackwater fever is still considered on fairly good grounds to be a complication or sequela of malaria. It is most often found in endemic and hyperendemic malignant tertian regions but may be associated with benign tertian or quartan malaria. Plasmodia are found in the peripheral blood in about half the active cases. Blackwater may appear in individuals who have left the tropics and are residing in temperate or cold climates. It may develop subsequently to artificially induced malaria. KITCHEN and SADLER (1945) have recently described such a case in which three plasmodial species were used therapeutically in succession *P. falciparum* being introduced by mosquito bite. In spite of treatment *P. falciparum* persisted in the peripheral blood for about five months. At the end of this period the patient was given a further course of quinine therapy and developed blackwater fever some hours after the first day's treatment. All the malarial strains used in this case were well known and none had any previous history of being associated with haemoglobinuria. The authors therefore suggest that the prolonged parasitaemia may have been an aetiological factor. The quinine administration may also have been significant. The relationship of quinine administration to the onset of blackwater fever has frequently been noted. For instance in the West African Command in 1941-49 haemoglobinuria developed in a high proportion of cases during oral quinine therapy for malignant tertian malaria. Moreover FINDLAY is quoted (SKINNER and HAINE 1945) as stating that in the same Command the incidence of blackwater fever diminished considerably after the introduction of mepacrine in place of quinine for treatment and suppression of malaria.

Various attempts have been made from time to time to determine the rôle of antimalarial drugs in the genesis of blackwater fever but apart from clinical observations such as those mentioned above the results of experiments on these lines have been equivocal. Recently ZYLMANN (1944) compared the lytic action on human red cells (both from normal and malarial subjects) of equivalent solutions of quinine and atabrin and observed that whereas quinine had a lytic effect on all cells atabrin acted more vigorously on cells from malarial patients. He concluded that atabrin had a true lytic effect. Most authors

however are agreed that atebuin has in fact, very little effective haemolytic action either when given in massive doses or in small doses over long periods (MAGRAITH and HAVARD 1945 Army Malaria Research Unit 1945 etc.)

Haemolysis

The most striking phenomenon in blackwater fever is the intense haemolysis which involves both parasitized and unparasitized cells. Such haemolysis is closely related to that seen in relatively minor degrees in malaria uncomplicated by haemoglobinuria. The mechanism of its production is not understood. No identifiable circulating haemolysin has so far been isolated, although the early experiments of FOY and KORVI led them at first to conclude that a "circulating haemolysin" existed in the circulation of the blackwater fever patient. These workers (1941) transfused normal red cells into an actively haemolyzing case of blackwater fever and found that the introduced cells were destroyed very rapidly and were therefore apparently as susceptible to lysis as the cells in the patient. An extension of these experiments by FOY and his colleagues (1945) showed that cells from a blackwater fever patient were equally readily destroyed in a normal circulation and further that the plasma from an actively haemolyzing case of blackwater fever did not precipitate a haemolytic crisis when injected into a patient suffering from malignant tertian malaria. These authors have therefore concluded that in blackwater fever the fundamental factor is probably

extracellular and can haemolyse normal cells as well as bring about changes in the blackwater fever cells that render them susceptible to destruction, even in normal circulations. This latter point is emphasized by the further observation of FOY and KORVI (1943) that blackwater fever cells are more fragile than normal cells in a lysolecithin system although as other authors have also reported, their fragility in saline is normal. This increased susceptibility of blackwater fever cells *in vitro* to lysolecithin indicates that this substance may play a part in the haemolysis of blackwater fever possibly by its action on the lipid-protein complex of the cell membrane. There is some evidence *e.g.* the appearance of spherocytes (FOY and KORVI 1943 and others) that this latter may be altered in blackwater fever with concomitant changes in permeability.

A splenic factor has often been considered as a possible agent in the lysis occurring in blackwater fever mainly on the analogy of the part played by this organ in other haemolytic states. VINT (1941) for instance has pointed out that enlargement of the spleen might increase the degree of separation of erythrocytes and plasma in that organ (KILISLY 1934 FAHRÆUS 1939). Such increased separation would work with existing anaemia (such as for instance that occurring in malignant tertian malaria) towards reducing the effective erythrocyte-plasma interface so that the so-called stabilizing substance (FAHRÆUS) which is thought by some to be lysolecithin* would be ineffectively adsorbed and thus become potentially active as a lytic or pre-lytic agent. This possibility has been recently discussed by FOY and KORVI (1943) and in more detail by GEAR (1946). The latter author further suggests that the spleen may function in blackwater fever as a reservoir of a hypothetical autohaemolysin (see later). This haemolysin would accumulate when the splenic circulation was impeded, as it is in the enlarged spleen of malaria and might be thrown out suddenly into the general circulation by splenic contraction thus accounting for the sudden onset of haemolysis often seen in blackwater fever.

LASER and FREIDMAN (1945) have recently isolated a haemolytic substance from human plasma which is nitrogen- and phosphorus-free and cannot therefore be lysolecithin. *In vitro* haemolysis brought about by this agent is inhibited in a remarkable way by antimalarial drugs, and Laser suggests that malaria parasites at some stage of their development produce a metabolite closely related to this natural haemolytic substance.

SMITH and EVANS (1943) consider that changes in blood pH may affect the rate of haemolysis. These authors found red cells resistant to saline haemolysis in alkaline solutions and highly susceptible in acid solutions. They suggest therefore that the degree of acidosis occasionally met with in blackwater fever may account for the increased haemolysis. Similar effects of pH have been noted by DACIE and RICHARDSON in cases of chronic haemolytic anaemia with nocturnal haemoglobinuria and recently BIRNBAUM and his associates (1945) have shown that the addition of alkali to bile solution delays its lytic action on both normal and malarial red cells. The latter authors conclude from their experiments that although acidity may thus play some part in haemolysis, sensitivity to lysis is primarily a function of the cell itself and not of its external environment.

An alternative hypothesis has been put forward by MAEGRAITH FINDLAY and MARTIN (1943) who discovered that animal tissue contains a heat labile lytic agent which is normally inhibited by factors present in tissue washings and serum. They suggest that the rate of lysis occurring in an animal at any one time may be a function of the balance between the tissue lytic factor and its inhibitors. Sera from actively haemolysing blackwater fever cases were found by these authors to inhibit the lytic agent much less effectively than normal sera indicating that in blackwater fever the balance between the lytic agent and the inhibitory factors is shifted to the lytic side. In blackwater fever therefore there exists no abnormal lysis rather the lysis is simply a manifestation of excessive uninhibited activity of the normal lytic process. The mechanism of reduction of activity of the inhibitory factors in blackwater fever is unknown possibly the plasmodial infection or the exhibition of antimalarial drugs or both may be concerned. PONDER (1944) has repeated the experiments of Maegraith and his colleagues and has confirmed their findings as far as the lytic effects of tissue are concerned. He considers the tissue lytic agent to be similar to lysocleithin. BRICKMANN and WERTHEIMER (1945) have also confirmed the presence of the tissue lytic agent which however they consider is not connected with normal or pathological blood destruction. It is not unlikely that the lytic agent observed by Maegraith and his co-workers is identical with the crystalline haemolytic substance recently isolated from human plasma by LASER and FRIEDMAN. Evidence of a similar lytic factor has also been recorded recently by BROWN *et al* (1944) in the course of an investigation of the fate of transfused red cells in various forms of anaemia.

Recently GEAR (1946) has suggested that the lysis in malaria and blackwater fever may result from a haemolysin developed as the result of the plasmodial invasion of the red cells. On the analogy of the experiments of SCHWENTER and COMPTON (1939) who found that emulsions of homologous kidney and brain were autoantigenic if injected into rabbits after being mixed with bacterial toxins GEAR suggests that the red cell when invaded by plasmodia may become autoantigenic, giving rise to an autoantibody (haemolysin) which in the presence of complement is able to lyse homologous red cells. A somewhat similar suggestion has been made by BUTTS (1945) who believes that a factor concerned in the haemolysis of blackwater fever may be iso-immunization to an Rh like substance present in malarial plasmodia. His assumption is based on what he states to be the comparative incidence of blackwater fever and erythroblastosis foetalis in white and negro races. BENJANS (1944) has also pointed out the possible rôle of autoantibodies in blackwater fever considered purely as a haemolytic disease. He considers that the presence of such antibodies is indicated by the difficulties encountered in cross-grouping the blood of blackwater fever patients for transfusion.

OLIVER-GONZÁLEZ (1944) has suggested that the malaria parasite may contain an antigen related to human isoagglutinogens and that autoagglutination

which is frequently met with in blackwater fever may result from immunization with such a substance. There is some evidence that the malaria parasite can behave in this way, as α and β agglutinins are often increased during the disease. This author found cold agglutinins in the sera of two cases of blackwater fever. It is interesting to note here that BEXIAVS has demonstrated similar cold agglutinins in severe Raynaud's disease.

A good deal of the pigment liberated by haemolysis in blackwater fever is removed by phagocytosis by reticulo-endothelial cells and converted into bilirubin which is absorbed by the liver cells in the usual way and eventually appears in the bile. Some degree of hyperbilirubinaemia is thus not uncommon in blackwater fever. When the haemolysis is so severe that the normal mechanisms cannot deal with all the liberated blood pigment, the degree of hyperbilirubinaemia is such that the patient becomes jaundiced. Some of the excess haemoglobin pigment is passed in the urine as oxyhaemoglobin (red common in alkaline urine) or methaemoglobin (dark reddish brown common in acid urine) but some remains in the plasma in the form of oxyhaemoglobin and methaemoglobin.

FAIRLEY and BROWFIELD (1934) investigated the pigments present in the plasma of blackwater fever cases and found evidence to suggest that haemolysis was mainly intravascular, the plasma methaemoglobin being apparently derived from the haemoglobin of the lysed cells. These authors observed a further peculiar haemoglobin derivative in one of their cases which they later called pseudo-methaemoglobin. This pigment was found to be present constantly in severe blackwater fever and in a series of elegant experiments FAIRLEY (1938, 1939, 1941) showed that it is formed from free haemoglobin after massive intravascular haemolysis and can be synthesized in man and monkeys after intravenous injection of alkaline haematin. Methaem-albumin as this new compound is now called, does not pass through the kidneys. It is apparently ultimately removed from the plasma by the liver.

Renal Function

About half the deaths in blackwater fever are associated with kidney failure (STEPHENS 1937). Renal function may become affected at any stage of the disease independently of the passage of haemoglobin in the urine. Failure is indicated first in most cases by a reduction in urinary flow which may go on to complete anuria. Recovery from anuria is rare and is usually followed by polyuria which may last a week or more. During this period the concentration of the urine is greatly reduced indicating renal tubular damage.

There has been extensive controversy over the mechanism of the production of renal failure in blackwater fever. Some authors consider that methaemoglobin in the presence of acid urine and an adequate concentration of salt gives rise to insoluble acid haematin which deposits in the renal tubules and so mechanically obstructs the flow of urine. MARGRAITH and FINDLAY (1944) and others have however pointed out that anuria frequently develops at a time when no blood pigments are being passed, that the salt content of the urine in blackwater fever is nearly always well below normal and that the urine is often alkaline or neutral when anuria supervenes. Again, heavy albuminuria with acid urine by no means invariably leads to anuria. These and similar observations have led many authors to the conclusion that the anuria of blackwater fever cannot be adequately explained on the grounds of mechanical obstruction by haemoglobin products (GEORGOPOULOS (1933) JOURNE (1944) PETERS (1945) etc.). In the search for a more satisfactory explanation a great deal of attention has been paid to the action of circulating haemoglobin and (because of the similarity between the kidney failure in blackwater fever and that in crush syndrome)

myohaemoglobin on kidney function. For instance YULE GOLD and HINDS (1945) injected solutions of haemoglobin into rabbits which were secreting acid or alkaline urine and in which the kidney tubules were previously damaged either by temporary clamping of the renal pedicle (which was shown by SCARFF and KEELE (1943) to produce renal cortical lesions) or by previous poisoning with sodium tartrate. These authors concluded from their experimental results that precipitation of haemoglobin in the renal tubules is not primarily dependent on the reaction of the urine but on non specific functional abnormality of the individual nephron which could be produced either by the ischaemia or by chemical poisoning. Given the renal tubular damage and haemoglobinuria however pigmented casts were more common in animals secreting acid urine than in those secreting alkaline urine. BYWATERS and STEAD (1944) recently reported that myohaemoglobin from dogs can similarly produce renal damage in shocked rabbits excreting acid urine leading sometimes to anuria and death. These and similar experiments have shown that circulating haemoglobin and related pigments may under certain conditions be associated with renal failure but in otherwise normal animals injection of these pigments has been found to have very little renal effect.

The existence in many diverse clinical conditions of the symptom-complex of oliguria or anuria associated with nitrogen retention and inability to concentrate urine and frequently accompanied by degenerative changes in the renal tubules but not necessarily related to the passage in the urine of blood or muscle pigments has led MAEGRAITH and his colleagues to suggest that the renal failure in blackwater fever may be due to some cause other than the circulating pigment which is common to many other conditions. For reasons outlined below these authors consider that the basis of such kidney failure is renal anoxia.

ALLEN pointed out in 1926 that the histological picture seen in kidney failure in acute malignant tertian malaria was similar to that of the later stages of blackwater fever the outstanding feature being marked degeneration of the cells lining the renal tubules. Such changes were not due to the malaria parasites themselves which are usually scanty in renal tissue even when abundant elsewhere in the body. Many authors from time to time have tried to incriminate toxic substances liberated by the parasite during its development or by the destruction of red cells at sporulation, but attempts to define this malarial toxin which is presumably present also in blackwater fever have all failed. For instance LINTHAREFF (1937) suggested that plasmodia produced a toxin which reversibly combined with haemoglobin to form a compound which acted directly on the renal tubular epithelium giving rise to degenerative changes. He attempted to prove his theory by comparing the effects on the renal function of guinea-pigs of injection of haemoglobin solutions obtained from normal and untreated malarial subjects. His results and others of an equally equivocal kind leave the question of the existence of a soluble malarial toxin still unsolved. In the present stage of our knowledge it is therefore necessary to look elsewhere for the explanation of the kidney lesions in malaria and blackwater fever. RIGDON (1942) has put forward the view that the lesions of malaria result fundamentally from a state of anoxia in the tissues concerned. Such tissue anoxia may arise from lysis of red cells or interference with their oxygen carrying capacity or may develop as the result of alteration of the capillary blood flow through the tissue arising from stasis or mechanical obstruction (e.g. by autoagglutinated and parasitized cells) or from generalized vascular constriction or collapse such as is seen in shock. According to RIGDON's hypothesis therefore anoxia of the renal epithelium in blackwater fever may result in part from the malarial anaemia and in part from reduction in the effective tubular blood supply brought about not by physical obstruction by

agglutinated parasitized blood cells (which are rarely seen in large numbers in the kidney) but by changes in the intrarenal blood flow associated with peripheral vascular disturbances of a general nature. SCARFF and KEELE (1943) have shown recently that degenerative changes can be produced in the renal tubular epithelium of the rabbit by restricting the blood flow to the kidney and have noted the similarity between the lesions so produced and those seen in crush syndrome. Many authors have commented on the close resemblance between the lesions seen in the crush syndrome and blackwater fever (BYWATERS and BEALL, 1941; BYWATERS and DRALE, 1942) so that it is possible that renal ischaemia may also play a part in the production of lesions in blackwater fever. Changes in renal blood flow have not yet, however, been demonstrated in blackwater fever but there is some clinical evidence that they occur in other conditions in which the syndrome of renal failure may develop such as traumatic shock (LAUSON *et al.* 1944). The investigation of the renal circulation in malaria and blackwater fever by means of clearance tests would add considerably to our knowledge in this respect.

Treatment

Antimalaria drugs—Although the disease is generally considered to be a complication of malaria most authorities consider that antimalaria drugs should not be given in blackwater fever. However, where parasites are present it may be dangerous to leave the malaria untouched. There thus seems to be no reasonable argument against using antimalaria drugs under such conditions provided the drugs are not themselves possible haemolytic agents. As stated above quinine is suspect and there is similar evidence to show that primaquin may also actively stimulate haemolysis. There is, however, no evidence of any value indicating that atebriin is a haemolytic drug or has any effect on haemolysis *in vivo*. The drug can be taken as a suppressive for very long periods without haematological effects—it can be given in large doses orally or intravenously without haemolysis—it is said to stimulate the haemolytic effect of specific haemolytic amoebocytes (ZYLKAMP, 1944) but the evidence for this is poor. Finally, experience has shown that atebriin can be given safely in blackwater fever. If it is employed it should be given in adequate dosage and not limited to small and innocuous but equally ineffective doses as sometimes recommended.

When parasites are not found in the peripheral blood, antimalarial therapy is not indicated. Frequently parasites appear after haemolysis has ceased and the patient has begun to recover. Under these circumstances again atebriin is indicated in full dosage.

Replacement of fluid and salt—Fluid and salt may be lost by the patient in large quantities as a result of excessive sweating, vomiting or watery diarrhoea. As far as possible fluid loss (urine, liquid faeces, vomit) and fluid intake (including of course parenterally administered fluid) should be estimated and the intake must be roughly balanced against the output. It is a serious mistake to push fluids too vigorously—the patient, especially when anuric, can only too easily be waterlogged, with resultant oedema and circulatory complications (PARAMORE, 1945; *Bull. U.S. Army Med. Dept.*, 1945; MARGRAITH, 1945). Fluids should be given when possible by mouth. If vomiting or coma prohibits this intravenous infusion by drip of physiologically balanced saline solution is indicated. The infusion should be given slowly and the amount must be controlled by the output intake balance.

Transfusion—As a good working rule it can be reckoned that if the red cell count is 1.5 million per cmm the carriage of oxygen to vital tissues is dangerously reduced. This makes transfusion necessary. Replacement of red cells can be

carried out by transfusion of citrated blood by direct arm to-arm transfusion or by injection of a concentrated cell suspension in physiological saline. The injection of citrated blood is liable to give rise to severe reactions with rigors due to so-called pyrogens. Direct transfusion is difficult in tropical conditions owing to sweat dust etc. Injection of concentrated cells is the best method if facilities are available. The fluid given with the transfusion must be calculated in estimating the daily fluid intake. As pointed out elsewhere the agglutinins of the plasma may be increased in malaria and blackwater fever and autoagglutination is common. It is necessary therefore before transfusion to cross match the donor's corpuscles with the patient's serum and vice versa. Grouping is not in itself sufficient.

SMITH and EVANS (1943) have stated that transfusion is inadvisable when oliguria or anuria is present. This advice is apparently based on the possibility of lysis of the donor's cells. Such lysis does sometimes occur but it is seldom severe and must be risked if the patient's corpuscles are so few that the oxygen carrying power of the blood is seriously reduced.

Alkalis—Intensive alkali treatment of blackwater fever based on the mechanical blockage hypothesis of BAKER and DODDS (1925) was first employed by HANSCHALL in 1925. The object of such therapy is to produce an alkaline urine and so to minimize the precipitation and deposition in the renal tubules of haemoglobin and its derivatives so that mechanical blockage of the uriniferous tubules is prevented and anuria thereby avoided. Such therapy has been enthusiastically recommended and has had many advocates in recent years some of whom go so far as to advise enough alkali to produce Trousseau's sign (SMITH and EVANS 1943). MAEGRAITH and his colleagues have recently criticized the basic hypothesis upon which alkaline therapy is founded and have pointed out that since the introduction of this form of treatment the death rate from blackwater fever has risen not fallen. These authors point out that the frequently repeated advice that alkali should be given until the urine becomes alkaline is unsound since where kidney function is damaged the reaction of the urine may remain unaffected by large doses of alkali. In any case it is not established that anuria is less likely to develop if the urine is made alkaline (MAEGRAITH and HAVARD 1944). Alkalis are usually administered as sodium salts commonly the bicarbonate or citrate or both. In reasonable doses e.g. not more than 20-30 gm. in 24 hours these salts are not contra-indicated and may be useful in promoting mild diuresis. Given in large doses they may be dangerous (ARMY MALARIA RESEARCH UNIT 1945). Alkalis are best given by mouth, but may be administered intravenously as sodium bicarbonate solution (150 grains to the pint). Sodium lactate may also be given intravenously.

The use of alkalis has also been advocated for dealing with the acidosis which is frequently said to be present in blackwater fever. The available evidence does not altogether support this contention. Acidosis although occasionally reported (FAIRLEY and BROMFIELD 1933. FOY KOVDI and MOUMJIDIS 1941) is not commonly seen in either malaria or blackwater fever.

Other substances—The successful treatment of blackwater fever with anti-venene has again been reported recently by SINGH and SINGH (1943) but the evidence brought forward is unconvincing. BURKITT (1943) has used sodium luminal [Phenobarbitonum Solubile] grams 8 to 10 intramuscularly with good results and quotes a series of 30 cases of blackwater treated successfully by GREGORY with intravenous injection of 15 grains of that drug. GEAR (1946) believes that the apparent success of such treatment results from the sedative action of these drugs which minimizes splenic contraction and may thus prevent flooding of the circulation with (hypothetical) autolysin.

SUMMARY OF RECENT ABSTRACTS *

VII HELMINTHIASIS.

[Continued from p 701]

Nematodes

Hookworm Infestation etc—FERRO-LUZZI (p 478) claims that until recently the problem of ankylostomiasis has not arisen in Eritrea but that owing to the movements of troops and labourers from other countries parts of Eritrea are now becoming endemic foci.

SMIRNOV (p. 135) has made studies on the rate at which hookworm larvae penetrate the skin of the hamster

FLEMING (p. 48) reports a case of intractable diarrhoea with high eosinophilia due to hookworm infestation apparently contracted after a single exposure to infective mud.

From the study of the records of a large number of cases of hookworm infestation KAMMER (p 48) concludes that fever is a very uncommon symptom. Eosinophilia was a pronounced feature in a large proportion of patients admitted to a U.S. base hospital in the South Pacific during 1942-43. As a result of studies made on these cases ALLEN (p 49) concludes that hookworm infestation was largely responsible for this eosinophilia. CRUZ and DE MELLO (p 1020) report but cannot explain a diminution of the excretion of sodium chloride in the urine of patients with hookworm anaemia.

In *Army Medical Department Bulletin No 47* (p 742) it is noted that the recommended treatment for hookworm infestation [for adult British males, presumably] consists of 4 cc. tetrachlorethylene and 1 cc. oil of chenopodium this draught being taken on an empty stomach and being followed if necessary by a dose of Epsom salts a few hours later

* The information from which this series of summaries has been compiled is given in the abstracts which have appeared in the *Tropical Diseases Bulletin* 1945 v 42. References to the abstracts are given under the names of the authors quoted and the pages on which the abstracts are printed.

DUVOIR and BRUMPT (p. 913) describe the artificial infestation of patients suffering from polycythaemia with larvae of *Ancilostoma duodenale*. The effect of this infestation on the disease was apparently beneficial, the number of red cells being reduced and the symptoms relieved, in a few days.

EIKHORN *et al.* (p. 911) have made five surveys of children in the Gorgas Hospital Panama Canal Zone—they were infested with one or more of the common intestinal nematodes. MILLER *et al.* (p. 912) refer to these cases noting that there were some infections with *Strongyloides stercoralis*.

WHITEHILL and MILLER (p. 576) describe a patient in whose urine larvae of *Strongyloides stercoralis* were found on several occasions though they were absent from the faeces. The origin of the infection was not discovered. Treatment with gentian violet was successful. v. EXGEL (p. 49) describes a case of infestation with *Strongyloides stercoralis* in which apparent cure was obtained by means of gentian violet (1 per cent. solution) introduced slowly (50–60 drops per minute) into the duodenum. A dose of 250 cc. gave rise to continuous retching and slight collapse but subsequent daily doses of 100 or 50 cc. given more slowly for 5 days, apparently completed the cure. PALMER (p. 133) describes a case of infestation by *S. stercoralis* in which apparent cure was obtained by means of gentian violet given in enteric-coated tablets. The patient died (apparently of tuberculosis) but no *Strongyloides* could be found post mortem—larvae had been found in the faeces before treatment was started.

HASIMOV (p. 50) describes for the first time infestation of man by *Ostertagia ostertagi*, normally a parasite of cattle and sheep. He describes the specimen found. In comment LAPAGE suggests that the worm may have been merely a passenger in the human intestine.

TSUCHIYA and RELLER (p. 817) report a case of infestation with *Trichostrongylus* in the United States where it is exceedingly rare though not uncommon in the sheep- and goat-raising areas of India and in Japan. They discuss the identification of the eggs of *Trichostrongylus*.

Ascariasis etc.—GUHL (p. 51) writing in a Swiss journal remarks that human ascariasis has increased enormously since the end of the war of 1914–18 and he suggests that this may be due to increased consumption of uncooked foods which are often grown in gardens fertilized with human excreta. He describes two fatal cases in which these worms were found in the bile ducts within the liver. Treatment with anthelmintics is not capable of destroying the worms in the bile ducts and surgical removal of the worms with drainage of the bile ducts may be necessary.

CHANG and CHIN (p. 744) observe that in Szechwan China vegetables are grown in soil fertilized with human faeces and are frequently contaminated by the eggs of *Ascaris*. They have shown that the process of pickling in brine which is a common procedure for the preservation of these vegetables does not ensure that all the eggs are destroyed. The infection may therefore be spread by the consumption of pickled vegetables though other sources of infestation are no doubt, more important.

EIKHORN *et al.* (p. 914) discuss a series of children infested with *Ascaris* and seen at the Gorgas Hospital Panama Canal Zone—most of them were in hospital because of other diseases of which the commonest was malaria. As usual, there was a high incidence of *Ascaris* infestation in early life. The symptoms are discussed [but the association with other diseases obscures them] the authors commenting that anaemia is not one of them and that eosinophilia is no index of the severity of infestation. The drug of choice for treatment is hexylresorcinol. Details are given of cases in which *Ascaris* was regarded as the cause of death.

The complications due to *Ascaris* infestation as observed at autopsy are discussed by UNGAR (p 745) He reports eight cases in three of which there was intestinal obstruction with gangrene in one invasion of the common bile duct in one invasion of the pancreatic duct and in three toxic damage to the intestinal wall probably due to substances produced by the disintegration of dead worms In most of these the serious complications probably depended not so much on the numbers of worms as on the coincidence of other pathological factors Details of these should be sought in the original

GRAM and HICKS (p 818) have demonstrated that eggs of *Ascaris lumbricoides* are very resistant to sludge digestion either aerobic or anaerobic even after 6 months about 10 per cent of the eggs are still viable Drying in sludge kills them and they cannot survive a reduction of moisture to below 5 per cent Heating the sludge to 50°C for 20 minutes kills half the viable eggs and to 103°C kills them all

VINNITZKY (p 746) has introduced living or dead *Ascaris lumbricoides* and *Toxocara canis* into the peritoneal cavity of certain animals to study the reactions obtained The findings cannot satisfactorily be summarized, and those interested should consult the original abstract

MUKERJI and BHADURI (p 919) describe a case of gnathostome infection of the eye in Bengal The infection was associated with orbital cellulitis and iritis which cleared up when the worm was removed The authors think that this belonged to the new species previously described by MAPLESTONE In man both adult and larval forms may be found the natural hosts are the cat and the dog and man is probably infested by eating infested *Cyclops* or fish

Filariasis—CAUSEY *et al* (p 647) examined 5 000 persons at Belem Brazil where filariasis has long been prevalent an infection rate of some 12 per cent was found but the elephantiasis rate was only a fraction of this The chief vector is *Culex fatigans* which is also the commonest mosquito but *Anopheles darlingi* and *A. aquasalis* were also found infected in nature *C fatigans* breeds well in polluted water and one measure of control therefore would be the improvement of general sanitation and drainage

In American soldiers in the South Pacific ENGLEBORN and WELLMAN (p 819) calculate that the shortest period between infection with *B. bancrofti* and the appearance of symptoms was 3 months and that severe symptoms take 8 months to appear The earliest symptoms are general the local symptoms occurring later All the patients in this group had funiculitis many had orchitis and epididymitis a few had lymphadenitis and lymphangitis

KING (p 304) writes from an experience of 268 cases of early filariasis in American soldiers The incubation period appears to vary from 3 to 16 months The first symptoms are pain, swelling or redness of an arm or leg or pain and swelling in the scrotal region Sometimes there is slight fever and the later symptoms may be classified as lymphangitis of the trunk or extremities acute inflammation of the scrotum or its contents and enlargement of lymph nodes No microfilariae were found in the blood of these patients The author thinks that clinical diagnosis is reliable, but has had fairly satisfactory results from the use of an intradermal test

FOGEL and HUNTINGTON (p 53) describe the genital manifestations of early filariasis as they have seen them in members of the American forces in the South Pacific no microfilariae were found in the blood or tissue fluids Some constitutional symptoms were observed and the signs included swelling and oedema of the spermatic cord inflammation of the testes and adnexa hydrocele oedema of the scrotal skin and inguinal adenitis No satisfactory drug treatment was discovered but rest and support were beneficial Operations on hydrocele, hernia and varicocele are contra indicated

GLAUSER (p. 479) also discusses filariasis in American Marines who served in Samoa. He observes that the psychological aspect of the disease was of considerable importance but implies that the fears engendered were largely illusory—there is no evidence that impotence or sterility is caused, and it is improbable that elephantiasis will develop in these men. No form of treatment was found to be effective.

JOHNSON (p. 478) reports on filariasis in U.S. marines from the South Pacific. He makes the point that the longer the time these men spend in the United States after infection the greater the improvement in their condition.

HODGE *et al.* (p. 1020) found microfilariae in two of 268 American soldiers with filariasis. They estimate that in a detachment of soldiers exposed to infection for about one year though only 11 per cent were found to have typical signs, the rate of infection will eventually prove to be in the neighbourhood of 50 per cent. Descriptions of the clinical signs and of a skin test are given.

ZUCKERMAN and HIBBARD (p. 480) have examined lymph nodes removed from patients with early filariasis. They state that biopsy is not necessary for diagnosis in most cases but may be useful in some. Sections showed marked hyperplasia of the reticulo-endothelial cells with hyperplastic and obliterative endolymphangitis even in lymphatics in which acute lymphangitis had not clinically been present. This suggests a general reaction to a toxic product of the worm itself. Eosinophilia was intense in glands in which the filariae were also present, but not in others. There was no evidence that lymphangitis was due to bacterial infection. WARTMAN (p. 305) describes the pathological appearances of the lesions in lymph nodes and in lymphangitis from some of the patients mentioned by King above. There is granulomatous inflammation around the worms and in the lymphatic sinuses.

CLEARKIN (p. 915) describes the technique and results of a skin test for filariasis in which he uses an antigen prepared from *Dirofilaria immitis*. This test gave positive results in 91 per cent of a group of infected persons but has the disadvantage that it is not specific for *W. bancrofti*—it may be positive in subjects with *Loa loa* or *O. rotundus* or even with *Trichuris* or *Trichinella*. Nevertheless, a positive test in conjunction with clinical symptoms of filariasis in an area in which *W. bancrofti* is known to occur can be taken as confirmation of the diagnosis of filariasis. OLIVER-GONZÁLEZ and BERCOTITZ (p. 219) have tried a precipitin reaction in filariasis, with an antigen prepared from microfilariae of *W. bancrofti*. The results were poor.

BYRD *et al.* (p. 479) give an account of the mosquitoes of the Samoan islands, and of their relation to *W. bancrofti*. Larvae of the latter were found in *Aedes scutellaris pseudoscutellaris* [*Aedes variegatus*] and *Culex fatigans* but these larvae were in the infective stage only in the former mosquito in nature. VEXNER (p. 478) found *Aedes aegypti*, *Aedes scutellaris pseudoscutellaris* [*Aedes variegatus*] and *Culex annulirostris* on two islands of the Ellice group in which filariasis is endemic.

SCOTT *et al.* (p. 917) though recognizing that microfilariae have practically never been found in the blood of American soldiers who served in the South Pacific [but see HODGE *et al.* above] have tested the infectibility of certain mosquitoes indigenous to California. They conclude that *Culex fatigans*, *C. erythrothorax* and *C. tarsalis* would be vectors if opportunity occurred.

BROWN (p. 53) treated 12 patients infected with *W. bancrofti* with anthiomaline, 10–50 cc. (60 mgm. per cc.) being given over a period of 13–26 days. Of the 11 in whom microfilariae were found there was great reduction in the microfilarial count in 10 four to five months after completion of treatment. Anthiomaline is not the ideal drug for this disease but these results indicate that further investigations of its value should be made.

JAFFE (p 918) notes that X-ray therapy in cases of filariasis does not appear to influence the course of the disease though some small benefit is given

YU and MAO (p 747) record *H. malayi* infection in a man who was reported never to have lived outside the provinces of Hupeh and Szechwan in China. *Culex fuscans* is susceptible to infection with microfilariae of *H. malayi* but HU (p 918) thinks that it would not be important in the lower Yangtze region because it seldom enters houses or feeds on man.

FRANKS and STOLL (p 916) describe a technique for the isolation of microfilariae of *D. immitis* and the preparation of an antigen from them for use in a precipitin test Parallel tests with an antigen prepared from adult *D. immitis* gave comparable results but the authors think that the larval extract actually obtained was not so strong as the larvae were capable of furnishing

SCHNELLE and YOUNG (p 52) have investigated the periodicity of microfilariae of *Dirofilaria immitis* in dogs The microfilariae appear in the blood about 8 months after infection and there are two daily peaks, the maximum being in the evening This pattern can be changed by altering the time of the principal meal of the day exercise has no apparent effect The authors quote evidence which suggests that the spleen is a reservoir for microfilariae.

BRADY *et al* (p 747) have traced the fate of injected antimony in dogs infected with *D. immitis* by using compounds prepared from radio-active antimony Nearly all the antimony left the blood in a few hours and the greatest concentrations were found in the liver and thyroid Antimony was also found in the adult worms After 36 hours the amount excreted in the urine might reach 20 per cent of the total injected.

CULBERTSON and ROSE (p 136) have found Neostam and Neostibosan to be effective against the filarial worm *Leishmanoides carinii* of the cotton rat.

NETTEL (p 54) notes that microfilariae of *Onchocerca* may be found in skin or subcutaneous tissues far from the site of a nodule and that on the other hand even in the presence of nodules the skin may be negative if the worms are immature or unfertilized GERMAN (p 819) describes a silver stain which gives better definition of larvae of *Onchocerca volvulus* than those commonly used He describes the morphology of the larvae as displayed by this stain.

RODHAIN (p 820) describes the pathological appearances of the lymph glands and skin in cases of onchocerciasis

GARRATT (p 649) describes two patients in Nigeria each complaining of upper abdominal pain, and in each of whom liver puncture revealed the presence of large numbers of larvae of *Acanthocheilonema perstans* though these were not found or were scanty in the peripheral blood. He therefore thinks that this infection was the cause of the symptoms The second patient was treated with anthiomaline and the numbers of larvae in the liver diminished greatly

RODHAIN (p. 821) has found *Agamofilaria streptocerca* in Africans of the Belgian Congo

Enterobius infestation—LANE (p 400) discusses infestation with *Enterobius* showing that much is still to be learned about its life-history and that treatment and prevention of infestation are still far from satisfactory

MILLER and EINHORN (p 578) discuss *Enterobius* infection in children seen at the Gorgas Hospital in the Panama Canal Zone. There is apparently a relatively high incidence in white children as compared with negroes and those of mixed races in spite of the better living conditions of the whites This has been observed before in the United States Treatment by tetrachlor ethylene was useless quassia enemata were valuable but gentian violet was the best drug

SCHÜFFNER and SWELLENGREBEL (p. 922) have devised a method of examination which in their hands has given better results than the NIH swab and

other techniques. They use a glass pestle ground slightly rough with which they massage the perianal skin moistened with water. The emulsion thus formed is transferred to a slide and either examined under a coverslip or dried and subsequently examined in cedar wood oil. This method is much quicker than the NIH technique and the authors claim that a simple washing procedure removes all *Enterobius* eggs from the pestle. By the pestle examination more positive results are usually found than by other techniques and more eggs are seen. The same authors (p. 924) discuss further the detection of eggs of *Enterobius* in various situations. They produce more evidence that the pestle method is better than the NIH swab method, pointing out that the preparation of the faecal emulsion which results from the use of the pestle breaks up the clusters of eggs and facilitates detection. Examination of dirt from beneath the finger nails shows eggs quite often but cannot replace the anal examination. The fact that eggs are found there has an epidemiological importance. Samples of dust from schools in Amsterdam have shown very large numbers of eggs especially in water-closets and in dining rooms but it is doubtful if eggs found in dust can develop if swallowed. For the examination of dust the authors prefer a flotation method with zinc chloride solution of specific gravity 1.33. Many details of technique are given in this paper.

PETERSEN and FAHEY (p. 920) have made an extensive survey of *Enterobius* infection in patients in a State mental hospital in the United States. Examinations repeated many times in subjects who gave negative results were made by applying microscope slides to the anal mucosa and the muco-cutaneous junction as this technique was found to be as accurate as and much more rapid than, the standard methods. In all, 59 per cent. of the inmates were infested, but the rate was much higher in those with chronic mental illness. Treatment with gentian violet repeated if necessary, was very successful. Details of the doses used are given in the original abstract.

In a study of the effect of different temperatures and degrees of humidity on the eggs of *Enterobius vermicularis* HELLER (p. 579) has shown that the optimum conditions for development are a temperature of 34-36°C and a humidity of 90-100 per cent. Higher and lower temperatures and dry conditions reduce the proportion of eggs able to hatch out infective larvae. Ventilation and drying of rooms therefore reduce the chances of spread of this infection. The conditions on the perianal skin appear to be close to the optimal for development.

LATIENDA and CARPANELLI (p. 137) discuss the question of appendicitis and infestation with *Enterobius* without arriving at any firm conclusions.

Trichiniasis.—PICOUREY (p. 400) reports an outbreak of trichiniasis in Beyrouth which is practically the only part of Lebanon in which pigs are reared. MÖRNING (p. 401) quotes evidence which shows that trichiniasis is very rare in the pigs of South Africa.

MAZZOTTI (p. 219) has found that compression of 10 gm. of muscle gives better results in the detection of *Trichinella* infection than compression of a smaller quantity and digestion of a larger. As a result of his investigations he estimates the incidence of this infection in Mexico City at about 12 per cent.

MAZZOTTI and LOZANO HURE (p. 55) have carried out a series of tests for trichiniasis in Mexico by means of the intradermal reaction of Bachman. They give details of their results but point out that these vary according to the standards laid down by different authors for a positive result. It is evident that more precise data are required before this test can correctly be evaluated.

GAASE (p. 481) reports a case of infection with *Trichinella* in which the complement fixation test was positive 15 days after the first appearance of symptoms. The test was also positive with cerebrospinal fluid of the patient,

who had shown signs of meningeal irritation and cerebral involvement due probably to toxins since no larvae could be detected in the brain substance.

TALICE (p 305) discusses the symptoms of trichuriasis there is no typical picture but oedema of the face or of other parts muscular pains diaphragmatic signs loss of weight digestive hepatic or gastric signs and eosinophilia are relatively common.

WENDEROTH (p 482) writes of the lesions of the cardio-vascular system in trichuriasis noting particularly the occurrence of thrombosis in the lung mesenteric veins sigmoid sinus and saphenous vein Myocarditis is common but no larvae were seen in the heart muscle in the series of cases in the German army under consideration.

MATOFF (p 579) has investigated the effects of introducing larvae of *Trichinella* into dogs by various routes in relation to any possible age immunity. The original abstract should be consulted.

LISBÔA (p 817) reports infestation with *Diactophyme renale* [*Eustrongylus gigas*] the largest of the parasitic nematodes in a woman who passed a male worm in the urine. Infestation with this worm is very rare and its life history is not known.

HAWKINS and COLE (p 912) describe work on the precipitates which form round the body orifices of exsheathed larvae of certain parasitic nematodes when they are immersed in the serum of previously infected animals.

DOELEMAN H. De malaria-epidemie te Middelburg in de jaren 1940 tot en met 1945 benevens een onderzoek van parasietendragers. This book is reviewed on p 875.

Soto H. Reconocimiento paludico en una region del Valle de Medellin Antioquia Colombia SA [Malaria Survey in the Medellin Valley Antioquia, Colombia.] 25 pp 6 graphs 5 maps & 9 pls [51 refs] 1945 Oct Bogotá Talleres Graficos Mundo al Dia.

This is a malaria survey report of Medellin and Itagüí two towns whose suburban extensions have met making them a single agglomeration of 173 300 inhabitants. It lies high up in the middle of the valley of the Medellin River Colombia the inhabited area ranging from 1 455 to 1 950 metres above sea level. It has a very equable climate the annual mean temperature is 22.4°C with very slight seasonal variation.

An examination of 3 700 individuals from 5 to 19 years of age revealed a spleen rate of 22.1 per cent. Malaria parasites were found in the blood of 309 individuals 8.3 per cent. *P. vivax* 289 *P. falciparum* 35 (15 mixed infections). *P. malariae* was not seen. Four species of *Anopheles* were found *A. eiseni*, *A. pseudopunctipennis*, *A. punctimacula* and *A. argyritarsis*. *A. eiseni* was found breeding in only a limited area which is not malarious. *A. pseudopunctipennis* and *A. argyritarsis* were found breeding in abundance. *A. pseudopunctipennis* latter species formed more than half of the total anopheline larvae identified. Neither of these two species appears to have any predilection for human blood and neither was found frequenting human dwellings in any numbers. They are unimportant as vectors of malaria in Medellin. *A. punctimacula* on the other hand predominated in captures in human dwellings. Of 684 females so captured oöcyts were found in 12.18 per cent. It is the chief malaria vector in Medellin and Itagüí.

BLACK, R. H. A Preliminary Note on the Cultivation in Vitro of New Guinea Strains of Human Malarial Parasites. *Med J Australia* 1945 Dec. 29 v 2, No. 26 500-501

Blood serum is obtained by placing 20-30 cc. of blood in a large test tube containing 0.1 cc. of 50 per cent glucose solution, and stirring for 5 minutes till defibrination is complete. The serum is separated by centrifugation and placed in a flat bottomed tube about $\frac{1}{2}$ inch in diameter to give a column of serum $1\frac{1}{2}$ to 2 inches high. Red cells infected with *P. falciparum* are obtained from beneath the leucocyte layer after centrifugation. These are introduced into the bottom of the serum tube, which is incubated at 37°C. During the course of 28 hours schizogony followed by invasion of new red cells, was observed. At 78 hours forms which resembled gametocytes appeared. At five days parasites were scanty but subculture into fresh serum containing red cells and glucose gave a result similar to the initial culture. C M Wenyon

HEIDELBERGER, M., MAYER, M. N & DEMAREST C. R. Studies in Human Malaria. I. The Preparation of Vaccines and Suspensions containing Plasmodia. *J Immunology* 1946 Apr v 52, No 4 325-30 1 fig & 2 pls.

As the authors point out little is known about the chemical and immunological properties of human malaria parasites, largely on account of the scarcity of material for study. During the recent war concentrates of parasites were prepared from heavily infected human blood by the method of differential centrifugation and by the use of an unsymmetrical magnetic field, which acts on the haematin and related malarial pigments. The antigens were prepared in an attempt to terminate relapses in chronic benign tertian malaria by vaccination of patients for use in prophylaxis, and for studies on the immunological properties of the parasites themselves. In the first method, in which all operations were carried out in the cold with aseptic precautions the separated red cells were washed in formalized saline lysed in chilled water saturated with carbon dioxide and the dissolved haemoglobin was removed after the solid particles had settled. By centrifugation at suitable speeds the leucocytes and stromata of red cells were removed in turn. Several washings with a dilute merthiolate solution removed formalin from the final product. In the case of blood infected with *P. vivax* the best results were obtained when large pigmented forms were present and 15-20 hours were required to deal with a 500 ml. sample.

The second method of separation, which is of academic rather than practical interest was based on the observation of previous workers that Kupffer cells loaded with ferric oxide could be separated from tissue cells in a magnetic field. The present authors found that the pigment of infected cells behaved differently in a magnetic field from the haemoglobin of the normal red cells and that parasitized cells in small volumes of blood could be concentrated by this means. An unsymmetrical magnetic field was obtained by the use of one pole-piece in the form of a cube the other being wedge-shaped. A cell containing 20 ml. of citrated, parasitized blood mixed with 10 ml. of 0.3 per cent. merthiolate in

saline was moulded around the thin edge of the wedge-shaped pole-piece and exposed to an intense magnetic field. Pigmented parasites were drawn towards the edge of the pole-piece and formed a thin brown streak on the wall of the cell. Convection currents were avoided by cooling with a fan and the blood was so diluted that red cells settled in 6-12 hours. The brown streak containing also some red cells was separated along with the supernatant fluid and centrifuged. In the case of blood infected with *P. malariae* 20 per cent of the parasitized cells were recovered by this means with a 140-fold concentration. In the case of *P. vivax* the recovery was 25 per cent with a 15-fold concentration.

ROMEO VIANONTE J M. Los anophelinos de la Isla de Gran Canaria. [The Anophelines of the Island of Grand Canary] *Rev Sanidad e Hig Publica* 1946 May v 20 No 5 449-55 17 figs. (15 4 coloured on 5 pls.)

During an investigation of malaria in the island of Grand Canary [see this *Bulletin* 1946 v 43 283] the author examined 123 adult specimens of anopheline mosquitoes of which 96 were *Anopheles (Myzomyia) hispaniola* and 27 were *A. (Myzomyia) sergenti* the figures suggest a predominance of the former species as was noted by CHRISTOPHERS (*Indian J Med Res* 1929 v 17 518). The mosquitoes were caught in the following places — Barranco de Arguineguín, Barranco de Ayagaures, Telde, Santa Lucía de Tirajana and Tejada.

The distinguishing characters of these two species are described and figured.

ROZEBOOM, I. E. & KNIGHT K L. The *punctulatus* Complex of *Anopheles* (Diptera: Culicidae). *J Parasitology* 1946 Apr v 32 No 2 85-131 7 pls. [34 refs.]

This paper reports interesting results and is an excellent example of the kind of investigation that is required to elucidate the relationships of the very closely related but distinguishable groups of mosquitoes which the practical culicidologist in the past has tended to designate as varieties of some well known species.

The authors believe that there are four good species of *Anopheles* specimens of which would before 1939 have been lumped together either as *Anopheles punctulatus* Dönitz or *Anopheles punctulatus* var *moluccensis* Swellengrebel & Swellengrebel de Graaf. It has already been pointed out by KNIGHT & FARKEP [this *Bulletin* 1945 v 42 688] that the form to which the name *moluccensis* applies was previously described by Laveran as *farauti* in 1902, and this name must therefore have priority. The four species are as follows — *A. punctulatus* Dönitz (= *punctulatus* of recent authors), *A. farauti* Laveran (= var *moluccensis* of recent authors), *A. kolensis* Owen [this *Bulletin* 1946 v 43 6] described from Guadalcanal and considered by the authors of the present paper to be the same as the intermediate forms (between

punctulatus and *farauti*) from New Guinea. A clonal Roseboom and Knight, a new species described by the authors in the present paper from a single female reared from a larva taken near Humbolt Bay, Hollandia.

The authors' conclusions are based on biometrical data derived from the examination of series of specimens many with associated larval and pupal pelts and many bred from known females. They admit that they have not carried out all the cross-breeding experiments required to prove that the "intermediate forms" to which the name *holoseris* applies, are not hybrids, but this test was handicapped by the fact that females of *farauti* would not feed in the laboratory, the cross between *punctulatus* male and *farauti* female was therefore impossible under the conditions of their experiments. No hybrids were obtained when *punctulatus* females were given blood-meals and opportunities to mate with *farauti* males though these females, on being given the opportunity to mate with males of their own species did so at once and produced fertile eggs.

DULANEY Anna D & WATSON R. B. Complement Fixation in Relapsing *Plasmodium vivax* Malaria. *Amer J Trop Med* 1945 Nov v 25 No 6 473-80 1 fig

These observations carried out at the Kennedy General Hospital U.S.A. relate to 394 patients suffering from relapsing *P. vivax* infections acquired in the Pacific war areas. All the patients were ambulatory except for brief periods during malaria attacks all were free from syphilis. The first group of 133 patients were studied during a six months period on them 287 coincident complement fixation tests and blood film examinations were made. On the second group of 261 patients 6,220 complement fixation tests were carried out.

The antigen used was prepared from pooled *P. knowlesi* parasites of monkeys [COGGESHALL and EATON this *Bulletin* 1939 v 36 404 DULANEY STRATMAN THOMAS and WARR, *ibid* 1943 v 40 11] Saline extracts of the dried parasites were used for all tests in the first group and a quarter of the tests in the second group. A phosphate buffer extract was used for the remaining tests [DULANEY and MORRISON this *Bulletin* 1945 v 42 352].

The results show that the complement fixation test is more sensitive than blood examination in detecting persistent subclinical infections (all the patients had received suppressive atabrin treatment). In the 6,507 coincident examinations there were 4,007 positive reactions 62 per cent but only 854 positive blood films 13 per cent.

The patients could be classified into serological groups: the positive pattern (continued positive) the negative pattern (continued negative) and the changing pattern group. Eighty-eight per cent of the positive pattern group relapsed as compared with 42 per cent of the negative pattern group. 79 per cent of the changing pattern group relapsed. Series of positive tests at some time were recorded for all these patients.

In cases of relapse the complement fixation to blood film ratio on the day of attack was 0.7:1 after three days the ratio was 16:1 and after 6 days 80:1.

A series of negative complement fixation reactions with negative blood films over a sufficiently long period suggests the possibility of clinical cure. This period is more than six months.

A conservative attitude toward the test is recommended, an attitude which recognizes its limitations but appreciates the possibilities of its correct use.

TUMULTY P A. NICHOLS E SINGEWALD M L. & LIDZ T An Investigation of the Effects of Recurrent Malaria. An Organic and Psychological Analysis of 50 Soldiers. *Medicine* 1946 Feb v 25 No 1 17-75 11 charts. [42 refs]

The object of this study of 50 soldiers who had suffered an average of 10 recurrent attacks of *P vivax* malaria was to determine what organic alterations the malaria might have produced and the relative importance of organic and psychological factors in the production of the symptoms displayed by these men

The soldiers six at a time were admitted to a small separate ward in an Army General Hospital in the Pacific area and each was studied during a period of 7 days Forty three of them were receiving suppressive therapy at the time of the study 40 with atabrin 3 with quinine. The examination of each was very complete detailed medical social and psychiatric histories complete physical examination complete blood study including fragility test urine and stool examinations serological test for syphilis kidney function tests liver function tests tests for adrenal cortical insufficiency basal metabolic rate electrocardiogram teleroentgenogram of the chest special ophthalmological and psychiatric examinations intelligence tests and selected tests to measure certain phases of fatigue The technique employed in carrying out these tests is described and the results are recorded in detail A complete summary of this long report is not possible here

There was no evidence in these patients that numerous attacks of chronic, recurrent *P vivax* malaria caused damage or dysfunction of the organ systems other than the debility from which they suffered all had been healthy young adults who had been exposed to reinfections for only six months and their attacks of malaria had been treated early and adequately In nearly all there had been loss of weight and they were easily fatigued Thirty-six patients had never complained of headache before the malaria 26 of these developed chronic headache Exertional dyspnoea was a common symptom. Anorexia and insomnia were complained of by 40 per cent of the patients

An analysis of the symptoms led to the conclusion that malaria was the prime factor in their production but the individual's adjustment to the malaria and concurrent situational factors contributed to the development perpetuation and intensification of symptoms. Once the symptoms had become fully developed the soldier was of little value to the army but if his morale remained satisfactory he was usually capable of remaining useful. Emphasis needs to be placed upon the handling of the person rather than simply of his malaria. Soldiers who have adjusted poorly in civilian and military life and to overseas service are likely to make a poor adjustment to malaria and to become incapacitated rapidly. Soldiers who develop chronic symptoms early in the course of the disease anorexia indigestion and insomnia should be removed from units where marked physical exertion is required their retention is harmful to themselves and to the malarial morale of their units. Minimal hospitalization reduced the tendency towards the development of neurotic patterns

Norman White

COOK C D & HOFFBAUER F W Liver Functional Impairment in Therapeutic Malaria with particular reference to the Unsuccessful Use of Methionine as a Protective Agent. *J Lab & Clin Med* 1946 Jan. v 31 No 1 56-64 4 figs [23 refs.]

Impairment of liver function has frequently been observed in patients undergoing malaria therapy The observations described were designed to

determine what protection, if any against such impairment is afforded by the addition of methionine to a general hospital diet

Twelve patients suffering from neuro-syphilis were inoculated with citrated blood containing *P. vivax* intravenously in 11 cases intramuscularly in one. The plan of the therapy was to maintain fever of over 103°F for a total of 50 hours seven to eleven paroxysms. None of the patients had previously had malaria and none had a history of jaundice or infective hepatitis. In no case was there any evidence of hepatic disease at the time of admission.

All twelve patients were studied with regard to liver function before during and after malaria therapy. The four laboratory tests used were cephalin-cholesterol flocculation, quantitative serum bilirubin the quantitative Ehrlich reaction and the bromosulphalein test. Six of the twelve patients received 81 gm. of methionine a day by mouth. All the patients were on a general hospital diet.

There was some evidence of disturbed liver function attributable to the malaria in all twelve patients. There was no evidence that methionine lessened that disturbance in any way. In ten patients functional abnormalities of the liver continued from one to three days after the termination of the malaria.

DE MELLO J P Malaria in Pregnancy *East African Med J* 1946 Jan. v 23 No 1 25-7

HANZLIK P J & CUTTING C C Clinical Trials with Quinine-Epinephrine Intravenously *J Amer Med. Ass.* 1945 Dec 29 v 129 No 18 1241-3

The investigation recorded was carried out to determine the safety of intravenous injection of quinine, as commonly used in the treatment of cerebral malaria and the safety and value of epinephrine in preventing the circulatory depression to which intravenous quinine gives rise

Intravenous injections of quinine-epinephrine were given to seven patients suffering from diseases other than malaria three of whom were in coma from various drug intoxications. Fleeting circulatory stimulation was observed, chiefly an increase in heart rate. The blood pressure was moderately though variably and temporarily increased in four patients. The comas were unaffected.

The authors conclude that quinine-epinephrine intravenously is a safe initial treatment for patients with cerebral malaria. The dosage recommended is 0.5 gm. of quinine hydrochloride or dihydrochloride (or 0.69 gm. quinine bisulphate) and 1 mgm. of epinephrine in 250 cc. of isotonic sodium chloride solution injected in not less than 30 minutes. Not more than two or three such injections, properly spaced should be given within 24 hours.

Norman White

FLOCH, H Le traitement économique du paludisme par la "quinine activée." [Economic Treatment of Malaria with "Activated Quinine"] *Bull. Soc. Path. Exot* 1945 v 38 Nos 11/12, 327-41 3 figs. [11 refs.]

The necessity of economizing limited stocks of quinine prompted the use of adjuvants to reinforce its antimalarial action. Preliminary trials led to the adoption of the following prescription —

Quinine hydrochloride	20 gm.
Resorcin	5 gm.
Methylene blue	0.5 gm.
Normal salt solution	250 cc.

After filtration through paper the solution is put up in 2 cc. ampoules, which are then autoclaved for half an-hour at 115-120°C. Each ampoule

contains 16 cgm of quinine hydrochloride and 4 cgm. of resorcin. The treatment consists of two intramuscular injections a day, each of two ampoules for six days. For a time all patients suffering from malaria admitted to the Cayenne General Hospital French Guiana were treated in this way. Clinical notes of nine such cases are given; they included both *P. vivax* and *P. falciparum* infections. The results were uniformly satisfactory. The author considers the results to be comparable to those obtained with three or four times larger doses of quinine without the adjuvants. The mixture can be given intravenously. There were no signs of intolerance.

Norman H kite

TRAGER W BANG F B & HAIRSTON N G. Relation of Plasma Level of Atabrine to Morphology and Motility of *Plasmodium vivax*. *Proc Soc Exper Biol & Med.* 1945 Nov v 60 No. 2 257-8.

When a single dose of atabrin of 200 mgm is administered intramuscularly to a patient infected with *P. vivax* at the time of the peak of concentration of the drug in the blood which occurs within an hour of its injection it is found that most of the larger amoeboid forms of the parasite have lost their motility and show a clumping of the pigment. Some hours later when the atabrin level in the blood has fallen many of the parasites will have recovered their motility and redispersed their pigment. It would seem in view of this recovery after a single dose of atabrin that when malaria is treated by intramuscular injection there is a need for repeated doses. After oral administration of quinine giving plasma concentrations of 6 to 10 mgm. per litre there was no loss of motility and no clumping of pigment within the first three hours.

C M Henyon

MAEGRAITH B G ADAMS A R D KING J D TOTTEY M M RIGBY D J & SLADDEN R A. Paludrine in the Treatment of Malaria. *Brit Med J* 1946 June 15 903-5 1 chart.

The authors treatment of benign and malignant tertian malaria with paludrine has already been reviewed [this *Bulletin* 1946 v 43 402]. Their present summary is as follows:—

Paludrine is a colourless slightly bitter drug belonging to a class of chemical compound not previously known to have antimalarial activity. Unlike most other antimalarial drugs it has been found to have an action on the exo-erythrocytic forms of the parasites in *P. gallinaceum* avian malaria.

It has been used successfully in the treatment of benign tertian malaria (both in relapses and in delayed primary attacks) and in acute attacks of malignant tertian malaria (both primary cases and relapses).

It has a very wide therapeutic range of activity. Doses of 10 to 750 mg and of 50 to 600 mg twice daily for 14 days have been used successfully in the treatment of benign and malignant tertian malaria respectively. No serious toxic side-effects have been observed with such dosages although occasional nausea and vomiting may occur at dosages of 500 mg or more twice daily.

The administration of single doses of 50 100 200 300 and 400 mg will produce clinical cure of relapsing and delayed primary cases of benign tertian malaria. Similar effects have been obtained with single doses of 400 mg mepacrine.

Twice-daily dosage regimes for 14 days have no greater effect on the relapse rate of benign tertian malaria than full courses of mepacrine. The administration of one dose of 100 mg weekly after treatment of the acute attack with a single dose of 50 to 400 mg has so far been found to keep the patient free from relapses. The effect of this therapy over a period of six months is being investigated.

J D Fulton

KING E. J. WOOTTON I. D. P. & GILCHRIST Margaret Estimation of Paludrine in Blood. *Lancet* 1946 June 15 888-7 1 fig

The level of paludrine in the blood during the ordinary course of treatment varies between 10 and 100 $\mu\text{gm.}$ per 100 ml. SPINKS & TOTTEY [this *Bulletin* 1946 v 43 400] developed a method for estimation of paludrine in blood, plasma and tissues, which depends on hydrolysis, followed by diazotization and coupling to give an azo dye. As little as 0.2 $\mu\text{gm.}$ could be estimated in solution in the ordinary way and it was possible to increase the sensitivity of the method by the use of special apparatus. The present authors have used an alternative method based on that described originally by BRODIE and UDEYFRIEND [*J Biol Chem* 1945 v 158 705] and later by MARSHALL and ROGERS [this *Bulletin* 1946 v 43 98] which is simple and rapid, and depends on laking of an acid dye. After extraction of paludrine from whole blood by a benzene-ethanol mixture brom-thymol blue buffered at pH 7 is added. Complete combination takes place between the base and brom-thymol blue within 5 minutes to give a product soluble in benzene, while excess of the dye remains in the aqueous phase. Instead of recovering the coupled dye from the benzene layer by shaking with alkali the authors have, for simplicity, estimated the decrease in brom-thymol blue of the aqueous phase, after making it alkaline so as to develop the deep blue of the dissociated indicator. For measuring optical densities a photoelectric colorimeter is of value and great care regarding cleanliness of apparatus and purity of reagents is recommended. The results of estimation of paludrine by the present method and that of the original authors were in good agreement
J D Fulton.

INDIAN MED GAZ. 1945 Oct. v 80 No 10 517 Paludrine-M.4888. [Editorial.]

In this Editorial note attention is called to the paper by DAS GUPTA, LOWE and CHAKRAVARTI [this *Bulletin* 1946 v 43 298] in which the compound M.3349 prepared by Imperial Chemical Industries was referred to as Paludrine. The name Paludrine however is now applied exclusively to the later compound produced by the same firm and given the number M.4888. The two compounds differ very considerably in antimalarial activity and in toxicity.

The paper by Das Gupta *et al* is probably the only publication in which M.3349 has been referred to as Paludrine and the name Paludrine is now reserved for M.4888.

MEAD J F RAPPORT M. M. SENEAR, A. E. MAYNARD J T & KOEFLI J B The Synthesis of Potential Antimalarials. Derivatives of Pantoyltaurine *J Biol Chem* 1946 May 163 No 2 465-73 [12 refs]

The views of FILDES [*Lancet* 1940 May 25 955] that drugs could limit the growth of bacteria by competing with an essential metabolite of the bacterial cell have received confirmation by other workers. Certain sulphonamides are active against malaria parasites *in vitro* perhaps by virtue of a similar effect. The present authors have applied the known facts to the synthesis of possible antimalarials. While there is little information at present available on the nature of essential metabolites of malaria parasites the *in vitro* experiments of TRAGER this *Bulletin* 1943 40 675 indicated that pantothenic acid is a growth factor for *P. lophurae*. Several inhibitors of pantothenic acid metabolism by bacteria are known and this fact suggested to the authors the desirability of testing them for antimalarial activity. For this purpose the preparation of optically active *d*-pantoyltaurine and derivatives has been carried out in compounds 1-7 R varied as follows —

A report of the tests with these substances in avian malaria will be given later meanwhile it is stated that *d*-pantoyltaurine (2) has shown definite activity *in vitro* J D Fulton

SPECTOR S HAVILAND J W & COGGESHALL, L. T The Ineffectiveness of Intensive Mapharsen, Bismuth and Carbarsone as Curative Drugs for Chronic Malaria. *Amer J Trop Med* 1945 Nov 25 No 6 463-7 [12 refs]

The reasons that prompted the investigations here recorded were the failure of all drugs hitherto tried to cure a large number of men suffering from chronic relapsing *P. vivax* malaria acquired in the Pacific war area, many of whom are entering the fourth year since infection. The fact that malaria recurrences ceased in a group of eight syphilis patients who were receiving a 26-week course of mapharsen therapy and the desire to decide beyond doubt whether therapeutically effective arsenic compounds in maximum tolerated doses could eliminate this type of malaria, and if not to recommend strongly against their further use.

Four groups of patients were selected. Group I consisted of 15 men each of whom received, during an acute relapse of malaria atebtrin, 3.2 gm. over a seven-day period and mapharsen 0.06 gm. intravenously thrice weekly, till each had received 20 mgm. per kilogram of body weight. In Group II nine men were treated with mapharsen and bismuth seven of them were luteic. The bismuth subsalicylate was given intramuscularly. Seven men in this group received a minimum of 30 mgm. mapharsen per kilogram of body weight. In Group III 48 patients received carbarsone a pentavalent arsenical by mouth. Ten men received carbarsone alone 0.5 gm. twice daily for 7 days. The remaining 38 received atebtrin in addition 0.2 gm. twice daily for 7 days. Group IV the control group consisted of 94 patients who were treated with atebtrin 0.2 gm. thrice daily for one day then twice daily for 6 days a total dose of 3 gm.

Within a month of the termination of treatment 7 of the 15 patients in Group I had both parasitic and clinical relapses—by the end of the third month only three had remained parasitically and clinically free of malaria. In Group II only four had remained free of a parasitic or clinical relapse at the end of 3 months. In Group III carbarsone alone caused the disappearance of parasites from the blood in all but one case but in four parasitaemia reappeared within 10 days—in the 3-month period all had had parasitic relapses but only 3 of the 10 had had clinical attacks. Among the 38 men who received carbarsone and atabrin at the end of 3 months there had been 24 parasitic relapses (63 per cent.) and 14 clinical relapses (37 per cent.). The control group of 94 patients who had received atabrin alone had in the same period 66 per cent. parasitic and 47 per cent. clinical relapses.

The conclusion is that arsenical preparations such as mapharsen and carbarsone are not indicated in the treatment of acute or chronic malaria.

GILLETTE H. P. S. The Progress of Malaria Control Measures in Trinidad and Tobago with special references to County St. David. *Caribbean Med J* 1945 v 7 Nos. 4 5 & 6 212-30

In a malaria survey of Trinidad and Tobago (this *Bulletin* 1944 v 41 445-7) 13 species of anophelines were found in Trinidad and three in Tobago. Since then another anopheline—*A. personi*—has been reported from Trinidad. *A. aquasalis* and *A. bellator* are the chief vectors of malaria in Trinidad, and *A. aquasalis* in Tobago. *A. aquasalis* readily enters human habitations—the time of greatest invasion is from 6.30 to 8.0 p.m.—a second less intense invasion occurring from 3 to 5 a.m. Its range of flight from breeding places may extend to three miles and possibly to five miles at certain seasons of the year. For purposes of larval control however a zone of one mile radius round the area to be protected gives good results. After biting, *A. aquasalis* does not remain long in the house. Animal barriers are of value in maintaining a low *aquasalis* malaria rate. Among permanent control measures, good results have been obtained by the construction of a culvert with a beak, or sea head, designed to keep the mouths of small streams open and by automatic flushing syphons. Paving ditches and levelling and filling have yielded excellent results in some places. The destruction of bromeliads in which *A. bellator* breeds by spraying with a one-half per cent. solution of copper sulphate continues to give good results.

A detailed account is given of the control measures carried out from 1941 to 1944 in the County of St. David, which forms the north-east corner of Trinidad. The success achieved is remarkable. St. David is now the least malarious county in the colony—formerly it was the most malarious.

BOVARTYCK, Marianna R. LINDSAY Ann & HELLERMAN L. Metabolism of the Malarial Parasite, with reference particularly to the Action of Antimalarial Agents. I. Preparation and Properties of *Plasmodium lophurae* separated from the Red Cells of Duck Blood by means of Saponin. *J Biol Chem* 1946 May v 163 No. 2, 523-33. [21 refs.]

These respiration studies with *P. lophurae* were undertaken to obtain information on the mode of action of antimalarials. Previous studies by others

on similar lines and with various species of malarial parasites had so far failed to elucidate the mechanism of inhibition of respiration by drugs. In order to eliminate the influence on metabolism of the red cell the parasites were freed from the latter by a modification of the saponin method of CHRISTOPHERS & FULTON [this *Bulletin* 1940 v 37 190]. The present authors indicate that the factors of chief importance in this method are the concentration of saponin used and the temperature at which parasites are incubated with this substance. Respiration measurements showed that the oxygen uptake of erythrocyte-free parasites was sometimes 70 per cent. of that of the original parasitized cells but varied more widely under different conditions of storage and experimental temperatures than the latter. This comparative instability of separated parasites could not be diminished by any treatment. The partial loss of respiratory activity was attributed to destruction of the duck red cells which themselves respire actively and lose their activity through the action of saponin. The reciprocal action of the metabolic activities on one another of red cell and parasite host must also be considered. Special buffer solutions were used in respiration measurements and for washing red cells the glucose usually present in the latter being omitted when other substrates were being studied.

The rate of oxygen uptake by intact parasitized cells varied with the stage of development of the parasite as shown by other workers [this *Bulletin* 1942 v 39 397 and 742 1943 v 40 674 1945 v 42 448]. With glucose as substrate the R.Q. of the separated parasites varied between 0.7 and 1.0. Only when lactate or pyruvate was used as substrate was their oxygen consumption similar to that observed when glucose was used. The inhibition of respiration by cyanide was complete but was less marked when azide was used. The inhibition could be counteracted to some extent by cresyl blue and other reversible dyes the former by itself inhibiting normal respiration to some degree. This increase in respiratory activity brought about by cresyl blue was believed to be due to its action on the red cell. An investigation of the inhibition of oxygen uptake by these separated parasites through the action of quinine or atabrin in presence of various substrates showed that it only occurred to any extent at the relatively high concentration of 0.001 M in each case and varied but little with the nature of the substrate. Cyanide-cresyl blue respiration was unaffected by these two drugs.

BOVARNICK Marianna R. LINDSAY Ann & HELLERMAN L. Metabolism of the Malarial Parasite, with reference particularly to the Action of Antimalarial Agents. II. Atabrine (Quinacrine) Inhibition of Glucose Oxidation in Parasites Initially depleted of Substrate. Reversal by Adenylic Acid. *J Biol Chem* 1946 May v 163 No 2 535-51 [21 refs]

In Part I above the authors noted that a relatively high concentration (0.001 M) of atabrin (quinacrine mepacrine) was required to cause marked inhibition of oxygen consumption by *P. lophurae*. Inhibition did occur however at much lower concentrations in the case of parasites previously depleted of substrate, in which case there was a well defined lag period before the oxidation of added glucose began which was reduced when lactate pyruvate fumarate or succinate were used as substrates. The measurements of glucose utilized and oxygen consumed during this period were in agreement. The nature of this inhibition by atabrin has now been investigated.

Erythrocyte-free parasites were obtained and depleted of oxidizable substrates by washing and shaking for a period of 100 minutes at 37°C. in suitable buffer medium. The parasites apparently suffered damage proportional to the length of the substrate free period. It was found that the induction period, before oxidation of added glucose begins could be reduced by the addition of

certain other substrates during the period of depletion, or along with glucose at the end of that period. The inhibition of oxygen uptake by atebirin in substrate-depleted cells was most marked when glucose was the substrate added and caused an 80-90 per cent inhibition of recovery in contrast to a 20 per cent inhibition in parasites not previously depleted of glucose. The marked effect on inhibition could be partially prevented by adenosine triphosphate (ATP) and adenylic acid (adenosine-5-phosphate) as well as by succinate and fumarate. These agents did not however appear to prevent cell damage. The inhibitory effect of atebirin under these conditions varied to some extent with the sample of blood used and may have been due to the removal of the free drug by solid constituents of the suspension. When washed parasitized cells were used which could not be wholly depleted of substrate like the separated parasites a similar sensitivity to atebirin was not apparent. A number of other drugs including quinine and plasmoquine, behaved like atebirin at low concentrations in preventing recovery of respiration in substrate-depleted cells. The specificity of action of adenylic acid in antagonizing the actions of atebirin led to an examination of phosphorus exchanges in cells and medium. It is probable that ATP and adenylic acid exert their effect in the speeding up of glucose oxidation by aiding the phosphorylation of this substance. Owing possibly to its impermeability 1-6 diphosphofructose was without effect on the parasites. FULTON (this *Bulletin* 1940 v 37 309) found that *P. knowlesi* was unable to oxidize hexose di- or mono-phosphate.] It is possible that the action of atebirin is due to interference with some phosphorylation reactions which are necessary before glucose can be utilized.

MARSHALL E K. Jr LITCHFIELD J T Jr & WHITE H J The Antimalarial Action in Ducks of certain Sulfanilamide Derivatives. *J Pharm. & Exper Therap* 1946 Mar v 86 No 3, 273-9

It was previously shown by the authors (this *Bulletin* 1943 v 40 223) that sulphonamides are active against *P. lophurae* infections in ducks when the blood concentration of these substances is maintained at a suitable level. Their action is antagonized by *p*-aminobenzoic acid. In the present investigation, and with similar methods the previous observations have been extended. White Peking ducklings weighing about 100 gm were infected with 100×10^6 red cells parasitized with *P. lophurae* which produced a peak of parasitaemia on the 6th day. Similarly 50×10^6 red cells infected with *P. calhemerium* gave a peak on the 4th-5th day. The drug was administered in the diet, and treatment which was given over a period of 5-10 days was started 24 hours before infection. The birds were kept in light and in darkness, alternately for 6-hour periods. The percentage reduction in parasitized cells at the time of peak-infection in controls was used as a measure of drug activity. On account of the wide variations in the degree of parasitization of the experimental birds the geometric mean of individual values was used for assessing the value for a group. Quinine was used as the standard drug and the ratio of its minimal effective dose (producing a significant reduction in parasitaemia) to that for other drugs served to measure their relative activity. On this basis an evaluation of slightly active drugs is possible.

By this test sulphadiazine was found to possess high activity relative to quinine in *P. lophurae* infections. The percentage of parasitized cells could not however be reduced below 1-2 per cent (compared with a 70 per cent infection in the controls at the peak period on the 6th day) whatever the dosage of sulphadiazine used. Quinine was much more effective in this respect probably on account of its more rapid action, for the effect of the two

drugs was similar when the peak of infection occurred on the 10th day and a graded response relative to dosage was then obtained. By using *P. cathe-merium* infections in the same hosts a marked difference in species susceptibility to sulphonamides was noted. Those in clinical use were not so effective against *P. cathe-merium* as against *P. lophuræ*. The activity of two halogen substituted sulphonamides was about equal in both infections and was considerably greater in *P. cathe-merium* than that of the sulphonamides in common use. Judging by the fact that the halogen derivatives were antagonized to a much lesser degree than the other sulphonamides by β -aminobenzoic acid their mode of action may be different

TRYPANOSOMIASIS

BURTT, E. Incubation of Tsetse Pupae Increased Transmission-Rate of *Trypanosoma rhodesiense* in *Glossina morsitans* *Ann. Trop. Med. & Parasit.* 1946 Apr v 40 No 1 18-28 3 figs. [18 refs.]

Most previous work on the transmissibility of *Trypanosoma rhodesiense* has stressed the fact that the vertebrate host and the parasite have important bearings on the frequency with which the tsetse vectors become infected. In this paper experiments are described which show that the temperature to which the pupae of tsetse flies are exposed may profoundly influence the infectibility of the flies by trypanosomes—this newly-discovered factor in the transmission of trypanosomes must be taken into consideration in regard to past and present work both in the field and the laboratory.

Pupae of *Glossina morsitans* collected in the field were hatched out in the laboratory some after keeping at laboratory temperatures and others in an incubator at 30°C (86°F). Unfortunately the author has not given the laboratory temperatures to which the pupae were exposed and it is to be hoped that he will do so but they were evidently below the incubation temperature as a comparatively large number of the experiments were made during the cooler season from June to August. The flies were removed from the incubator within 24 hours of emergence and thereafter kept like the others under normal laboratory conditions. The results are shown in tables and charts.

Of 21 068 flies which emerged from pupae kept at laboratory temperatures and were fed on animals—sheep reedbuck Thomson's gazelle or monkey (*Cercopithecus* sp.)—infected with *T. rhodesiense* 7 127 lived long enough for complete development of the trypanosomes in them, and 296 (4.2 per cent) showed infection of the salivary glands while of 9,335 flies which emerged from incubated pupae 3 352 lived long enough for complete development of the trypanosomes and 408 (12.2 per cent) showed infection of the salivary glands.

The infection rate of flies from incubated pupae varied according to whether they fed on infected sheep reedbuck gazelle or monkey but the difference was more marked with monkeys and Thomson's gazelle than with reedbuck or sheep. The results were all based on isolation of infective flies since the modified dissection methods of Lloyd and Johnson (this *Bulletin* 1934 v 31 215 1937 v 34 113) used at first was found to be unreliable.

Transmissibility seemed to be further raised if incubation of the pupae was prolonged. The time taken for the completion of the cycle of *T. rhodesense* in the fly was significantly shorter in those from incubated pupae than in those from normal pupae.

In all the experiments (110) with batches of flies from incubated pupae transmission resulted, though many were done in the cooler season but failure resulted in many of the experiments made with batches of flies from pupae kept at laboratory temperatures. No difference in longevity was observed between the two groups of flies.

VANDERPLAS (unpublished) in 1943 working independently of the author obtained similar results with *T. congolense* in both *G. morsitans* and *G. swynnertonii*.

A further question which arises from this work is whether cooling of the pupae would produce flies more resistant to infection with trypanosomes.

The practical importance of the results is discussed, particularly as it may influence the seasonal incidence of trypanosomiasis. Kenneth Mellanby

BURTT E. The Sex Ratio of Infected Flies found in Transmission-Experiments with *Glossina morsitans* and *Trypanosoma rhodesense*. *Ann Trop Med & Parasit* 1946 Apr v 40 No. 1 74-8 [15 refs.]

In these experiments at Tinde laboratory about twice as many male as female *Glossina morsitans* developed salivary gland infections. This was true whether the pupae from which the flies emerged had or had not been incubated [see above] and whether the infection was derived from sheep, reedbuck, gazelle or monkey. The male and female flies emerged in equal proportions from both incubated and unincubated pupae but in both cases there was a considerably higher death rate among female than male flies throughout their maintenance on Bruce fly boxes but not when towards the end of the experiments they were kept singly in bottles after having fed. Other workers have shown that both in the laboratory and in nature female flies tend to survive slightly better than male flies. It therefore appears possible that at Tinde a greater proportion of potentially susceptible (to infection) female flies were being weeded out by early death than males and that this might be responsible for the difference in the rates of infection in males and females.

DURR [this *Bulletin* 1930 v 27 847] found in experiments with *G. palpalis* that approximately equal numbers of male and female flies developed salivary gland infections. Female *G. palpalis* survived significantly better in his experiments than female *G. morsitans* did at Tinde and Burtt suggests that *G. palpalis* withstands mass confinement better than *G. morsitans*.

As the infection rate of tsetse flies is usually low, the proportion in which the sexes survive in experiments should approximate to that occurring in nature. As this was not the case at Tinde the question of the relative infectibility of the sexes remains unanswered and experiments with flies kept singly in bottles are needed. It is a question of practical importance both for the correct interpretation of experimental results and of what takes place in nature.

Kenneth Mellanby

DE AZEVEDO J. F. CAMBOURXAC F. J. C. & PIATO M. R. A doença do sono na Guiné em 1944 e observações sobre Ofídios, Culicídeos e *Phlebotomus* da Colónia. [Sleeping Sickness in (Portuguese) Guinea in 1944 and Observations on the Local Snakes, Culexines and *Phlebotomus*]. *Ann Inst Med Trop* Lisbon 1945 Dec. v 2 7-47 21 figs. on 10 pls. & 3 folding maps. English summary (4 lines).

The information given in this article is so condensed that it might almost be designated in itself an abstract. In November 1943 a Commission was set

up to investigate the prevalence of sleeping sickness in Portuguese Guinea and to devise methods of prevention because shortly before several severe cases of the disease had been observed among Europeans. The Commission started its work on 3rd January 1944 and returned on 23rd February having spent 50 days in the Colony. The amount of work attempted and accomplished during this brief period is astounding. They examined the natives domestic and wild animals caught and dissected specimens of *Glossina* investigated the clinical aspects of the disease and its influence on the general mortality in this paper they discuss the outlook and prophylaxis as regards the European and the native and report on a study of the snakes and insect fauna. As if this were not enough they were also asked to undertake in their stride as it were and as matters of secondary interest a study of the prevalence and extent of yellow fever and to collect evidence on the endemicity of malaria in the country.

The natives were collected in 48 places on an average about 200 in each in all 8543 were examined 397 of them had enlarged glands and were therefore suspected of trypanosomiasis and 61 of the glands were positive on puncture. The authors collected 3930 specimens of *Glossina* and dissected 1103 the proboscis salivary glands or intestine of any found infected were inoculated into laboratory animals. Ninety five per cent. (3720 of the 3930 collected) were *G. palpalis* 146 (9.7 per cent.) were *G. submorsulans* and the remainder 64 were *G. longipalpis*. Only 0.8 per cent. of the 1103 dissected showed infection by polymorphic trypanosomes of the *T. gambiense* group (salivary glands were infected in 6 (0.54 per cent.)). No domestic animals horses cattle or sheep were found to harbour trypanosomes infective for man. A gazelle was found with a trypanosome of the *T. gambiense* group.

The effect of infection with trypanosomes on the general mortality is said to be slight and the authors think that the strain of *T. gambiense* is one of low pathogenicity and is peculiar to the district. Individuals might be found heavily infected but nevertheless show practically no clinical signs. But, though the course of disease is long and apparently mild, fatal cases do occur. Comparing the present findings with those of Professor SEQUEIRA in 1932 they conclude that the disease has undoubtedly increased and spread. Until the reason for this extension is known, it is difficult in fact not possible to foretell the future in this respect. Prophylaxis consists in avoiding the fly belts as far as possible in travelling in the early morning or after dark, when the *Glossina* is less active and in the preventive use of Bayer 205 for those who have to enter the infected zones. It would, they suggest be well to set up a permanent mission to study and deal with the disease in Portuguese Guinea.

During their sleeping-sickness work, 10 species of snakes were caught one was a python seven were Aglyphae or Opisthoglyphae and so non poisonous two Viperidae were poisonous *Causus rhombatus* and *Bitis arietans*. The collecting of diptera was not included in the Commission's terms of reference but say the authors they did not lose the opportunity of examining them. Among their catches were *A. gambiae* *A. coustani* var. *tenebrosus* a *Culex* which could transmit filaria to man and dogs and certain protozoa parasitic in birds and two species of *Phlebotomus* namely *P. signatipennis* and *P. jallas*.

DEWEY H. M. & WORMALL, A. Studies on Suramin (Antrypol Bayer 205). 5
The Combination of the Drug with the Plasma and other Proteins. *Biochem J* 1946 v 40 No 1 119-24 1 fig [10 refs.]

This paper describes a continuation of work previously reported in this *Bulletin* 1939 v 36 688 1940 v 37 19. In this earlier work it had been shown that much of the Suramin found in the serum is in combination with proteins. The methods used to estimate Suramin do not differentiate between unchanged Suramin and degradation products or other substances which produce aromatic amines when hydrolysed by acid. Suramin combines with proteins quickly (in a few minutes). Much of the Suramin bound to proteins of human serum remained bound even after long extraction with methanol or aqueous ethanol. The amount bound varied in different experiments, but in one a fully extracted preparation still contained 5 per cent of Suramin (i.e. 3.5 mol. Suramin per 1 mol. protein of mol. wt. 100,000). The original concentration of Suramin in these mixtures of serum and Suramin was 1-2 ml. Suramin solution (0.2-0.6 per cent) in 20 ml. serum [i.e. of the order of 0.01 to 1 per cent.]. In some experiments with gelatin and casein from 70 to 90 per cent of the Suramin originally present became bound to these substances, but appreciably less was fixed by the serum protein. When Suramin is hydrolysed by acid the absorption of the degradation products by serum protein is much less than that of the original Suramin and the absorbed material can easily be removed by extraction with methanol. When hydrolysed Suramin is injected intravenously into rabbits almost all of it disappears from the blood in 6 hours when unchanged Suramin is injected considerable amounts persist in the blood for 90 days. Unhydrolysed Suramin is retained in the tissues of treated rabbits for many days hydrolysed Suramin is not retained in this way.

[There is some evidence that Suramin also combines with trypanosomes since trypanosomes which have been exposed to Suramin and then washed are no longer infective for animals, although they remain motile *in vitro* for over 24 hours at 37°C see HAWKING this *Bulletin* 1939 v 36 742.] F. Hawking

DIAS E. Aceso de 254 casos de doença de Chagas comprovadas em Minas Gerais. [Observations on 254 Cases of Chagas's Disease in Minas Gerais.] *Brasil Medico* 1946 Feb 2 & 9 v 60 Nos. 5/6 41-4

These brief notes refer to 254 cases of Chagas's disease seen in the States of Minas Gerais up to 28th December 1945. Of the total, 118 were males 136 females 168 were whites 40 were negroes and 46 half-castes. The ages of those infected are given showing that no age is exempt 33 were under 5 years, 50 between 6 and 10 years, 52 between 11 and 15 27 between 16 and 20 30 in the third decade 28 and 20 in the fourth and fifth respectively 16 were over 50 years of age. The primary lesion was on an eyelid in 38 cases among 57 studied elsewhere on the head in 8 (ears lips etc.) on arm or leg in 10 and one on the chest. The month of infection is noted in 47 but this is of little value where the total is so small suffice it to say that from September to February the cases numbered 5 6 6 6 7 and 8 in March and May there were 3 each, in April, July and August one in June none.

The diagnosis was made by xenodiagnosis in 168, by serological reactions (chiefly complement fixation, using a culture of the trypanosome as antigen) in 44 by blood examination in 40 and histologically post mortem in two.

There were 13 fatal cases among the total 254. Electrocardiographic tracings were made in 207 110 were normal 97 abnormal. A V block in 42, first grade in 30 second grade in 3 and total in 9 of the right ramus in 33. As regards residence 105 were living in the town of Bambuí 131 in the municipality

but outside the town and 18 further afield Details of the places of residence in the different suburbs 95 cases in all are given but are of local interest only

Estudo dos transmissores e breve relato de cinco casos [Chagas's Disease in São João Batista do Glória, Minas Gerais Study of the Vectors and a Short Account of Five Cases] *Brasil Medico* 1946 Mar 2 & 9 v 60 Nos 11 12 & 13 83-5 [11 refs.]

TORREALBA F J Investigaciones sobre enfermedad de Chagas en el Estado Guárico-Venezuela. [Study of Chagas's Disease in Guárico State Venezuela] *Gac Med de Caracas* 1945 Sept-Dec v 53 Nos 18/24 168-74 2 figs

Though other causes of myocardial mischief exist in the rural population such as malaria schistosomiasis syphilis ankylostomiasis and alcoholism the commonest is infection by *T cruzi*. The author quotes abundantly from the literature of the last 12 years instancing cases of sudden death from this cause such as the young baseball player apparently in excellent health running to a base and dropping dead another dying suddenly while working in a maize field Prior to 1935 such deaths were usually ascribed to syphilitic myocarditis Examination of persons perhaps showing no signs of disease clinically may reveal enlarged hearts arrhythmia extrasystoles intermittency and bradycardia as low as 23 per minute Cases are quoted in which four brothers were affected in this way another family with three brothers and two uncles It must not be thought that sudden and early death is invariable A case is referred to where a patient showed heart block and was proved by xenodiagnosis in 1939 to be infected but still carries on his work though with an intermittent signs of myocarditis tested by xenodiagnostic methods. Three of these gave positive results and one of the negative gave 3-plus Wassermann and Kahn reactions
H. Harold Scott

LAZZA S Sobre la pretendida relación de enfermedad de Chagas y bocio y cretinismo endémico A propósito de profilaxia del bocio [On the Supposed Relationship between Chagas's Disease and Endemic Goitre and Cretinism. The Prophylaxis of Goitre.] *Revista d Circulo Medico de Mendoza* 1945 Sept Oct Nov & Dec Nos 69/70 7 pp.

[This article rather stresses what is now well known that infection with *T cruzi* is not the cause of the thyroid conditions observed in districts where Chagas's disease also persists.] The author states that the idea of *T cruzi* infection being the cause of endemic goitre and cretinism ought now to be dropped that there is practically nothing to support it. He then quotes various workers CARINI PEREIRA COUTO SERPA BERCOVITZ GONZALEZ FLORIANI and others who have promulgated the error Professor LAZZA then speaks of one case a child of 7 months dying after a period of marasmus from syphilis and infected with *T cruzi* in whom leishmanial forms of the parasite were found in all the organs and tissues the thyroid among them. Since then among 1,200 cases of Chagas's disease the authors and his co-workers have not seen a single case of goitre consequent on *T cruzi* infection.

LEISHMANIASIS

ARCHETTI, I. Distribuzione e diffusione delle leishmaniosi nell'Africa Orientale Italiana. [Distribution and Spread of Leishmaniasis in Italian East Africa.] *Riv di Biol Colon* Rome, 1940 Dec., v 3 No. 6, 401-18, 1 map. [Numerous refs.]

NAJERA, L. Observaciones sobre la ecología de los *Phlebotomus* en su fase larvaria principalmente. [Observations on the Ecology of *Phlebotomus*, principally on Larvae.] Reprinted from *Rev Ibérica de Parasitología* 1948 Jan-Apr v 6 139-58 19 figs [29 refs.]

Reviewing general information on the food materials of the larvae of *Phlebotomus* spp. the author emphasizes particularly the observations of PARKOT [see this *Bulletin* 1933 v 30 308] and his co-workers that the larvae of some species will feed in captivity on the dried leaves of various trees. Such species include *P. papatasi*, *P. perniciosus*, *P. langeroni* var. *longicuspis*, *P. ariasi*, *P. sergenti*, *P. parroti* and, of Central African species *P. schwetzi*. He considers this phytophagy a true biological character and points out that it is of considerable interest in explaining the general limitation of *Phlebotomus* to rural and suburban districts.

In laboratory cultures the author found that larvae eat filter paper with voracity when it is impregnated with liquids carrying nutritive organic substances in solution. His breeding technique was as follows —

Females caught in bedrooms, with fresh or partially digested blood meals were put up in glass tubes of 5 cm. length and 2 cm. diameter. The bottoms of the tubes were lightly packed with cotton wool separated from the rest of the tube by filter paper disks cut accurately to fit the lumen and pushed down in contact with the wool, which was soaked in water. The mouths of the tubes were closed by a double layer of gauze and all the tubes were stacked vertically in petri dishes in a chamber of nearly 100 per cent relative humidity. Eggs were laid on the filter paper, some on the wall of the tube and were easy to examine and count with only low magnifications. About 70 per cent. of females oviposited and 20 per cent. deposited all the eggs contained in their ovaries. After oviposition the females usually died. Rearing of the hatched larvae was carried out in small unglazed baked-clay pots containing a layer of paste made from guinea-pig faeces over a layer of plaster. They were sunk in wet sand in a closed humid chamber.

Left after hatching in the tubes the larvae developed to the second, sometimes the third, instar and migrated downwards into the cotton wool but they did not attack the filter paper. They did however attack the filter paper when it was put in the pots with the nutritive medium. Apparently therefore the cellulose of the paper is only eaten when it is impregnated with nutritive liquids. This behaviour has so far been observed only in *P. papatasi* and *P. perniciosus*.

The author discusses these phenomena of phytophagy and papyrophagy in relation to the pre- and post-war distribution of *Phlebotomus* in Madrid. Before the war they were confined to the periphery of the city and the vicinities of parks and gardens. Since 1940 they have increased and are abundant in other localities in the middle of the city. Although to superficial observation there is little alteration of the city from its pre-war condition, there are scattered throughout it many bombed sites which have not been rebuilt. Such sites are often unroofed and are used frequently as rubbish dumps or public latrines. A selection of photographs and a list of such sites are given but the city was not examined systematically. Between 1942 and

1944 148 soil samples from 33 sites were examined and 14 were found to contain *Phlebotomus* larvae. Almost all the positive findings were made in the months June to September. He points out the danger of the introduction of infantile kala azar into cities under these conditions and recommends that bombed sites should be enclosed and all organic debris therein destroyed.

SEN GUPTA P C & CHAKRAVARTY V K. Penicillin in Cancrum Oris complicating Kala-Azar. *Indian Med Gaz* 1945 Nov v 80 No 11 542-5 2 figs. on pl.

It is well known that cancrum oris is one of the most fatal complications of kala azar giving a mortality rate of at least 50 per cent in spite of vigorous treatment with sulphonamides and pentnucleotide in addition to specific treatment for the leishmania infection. This unsatisfactory result has led the authors to test the effect of penicillin and in this paper they report on the treatment of six cases—five in children 2 to 10 years of age and one in an adult. Penicillin was administered intramuscularly or intravenously every three hours for about a week in doses of 10 000 units while local applications of penicillin solution containing 500 units per cc. were made for three weeks. In one case penicillin was administered as a lozenge. In addition specific treatment with pentavalent antimonials was carried out while general supportive measures were undertaken. Under the penicillin treatment the necrotic process was quite unlike that seen in the cases that recovered in previous years. It was rapidly checked and did not continue to extend while separation of sloughs occurred in all but one of the cases in 72 hours. All the patients recovered and the end results as regards scarring and deformity were fairly satisfactory. In one or two of the cases the course of penicillin was repeated to expedite healing. It is concluded that the system of treatment adopted in the cases described is likely to meet with better success than the treatments which were previously adopted.

CHAKRAVARTY K. C. The Treatment of Kala-Azar with Sodium Antimony Gluconate (Stibatin). Further Observations on the Treatment of Thirty-Two Cases. *Indian Med Gaz.* 1945 Oct v 80 No 10 507-11 8 charts [10 refs.]

In an earlier paper [this *Bulletin* 1945 v 42 17] the author with BURKE reported upon the treatment of 21 cases of kala azar with sodium antimony gluconate or antimony hexonate (stibatin of Glaxo Laboratories). In all these cases there was immediate clinical cure but the follow up was too short to justify any statement as to permanency of cure. The author of the present paper has followed up these 21 cases for six months. 18 had remained quite healthy and can be considered cured, while 3 had relapsed. He also reports on the treatment of 32 other cases of kala azar in patients varying in age from under 10 to over 40. In children under 15 the total quantity administered was ten times the age in cc. or 1 cc. for each year of age multiplied by 10. For older patients the standard total dose is 1.5 cc. (or 30 mgm. of the antimony compound) for each pound of body weight divided into 10 daily doses. In patients of such high weight that the total dose works out at over 200 cc. the number of injections may be increased. The drug is remarkably non toxic for in the cases treated there was an immediate reaction of palpitation in only one case while in two cases albuminuria developed after four and seven injections. This albuminuria disappeared when the course was interrupted and it did not recur when treatment was resumed. The 32 cases were followed up

for six months when it was found that only two had relapsed. The author concludes that the drug is specific in the treatment of kala azar and on account of its low toxicity and ease of administration owing to its being supplied in solution ready for injection it is specially useful when mass treatment is required.

SEN GUPTA P C & CHAKRAVARTY N K. The Treatment of Kala-Azar with Sodium Antimony-v-Gluconate Preliminary Observations. *Indian Med Gaz* 1945 Nov v 80 No 11 560-64 [18 refs]

In this paper the authors report on the treatment of 50 cases of kala azar in India, with sodium antimony gluconate in doses higher than those previously employed. The procedure adopted was to give daily intramuscular injection for 10 to 12 days of 15 to 20 cc in the case of adults or 6 to 15 cc. in the case of children. It was found that there was little irritation the patient being able to walk home within 15 to 20 minutes after the injection. An analysis of the actual doses employed in the 50 cases gave a total dosage as follows Children 3.7 cc. adolescents 2.7 cc. adults 2.1 cc. per pound of body weight. In seven patients the course had to be repeated. The immediate result of this treatment was very satisfactory as there was a clinical cure in 48 of the 50 cases. One of the failures was a case which proved resistant to all treatments and the other was in a case complicated by agranulocytosis.

In addition to the cases of kala azar two of post-kala azar dermal leishmaniasis in adults were treated by two courses of 10 or 11 injections at a week's interval. In both there was early and marked improvement.

All the cases treated are being followed up to determine if relapses do or do not occur

CAMPOS J A Intradermo-reacção de Montenegro precoce [Accelerated Montenegro Reaction.] *Arquivos de Hig e Saúde Pública* São Paulo 1945 Mar v 10 No 23 43-6 English summary (9 lines)

After the intracutaneous injection of leishmania antigen in the application of the Montenegro test for cutaneous leishmaniasis, an anaemic swelling is at first produced which later in positive cases becomes a red papule. In a varying number of cases the reaction is indefinite. The authors have tested in a series of eleven cases the effect of cupping the initial swelling for 3 to 17 minutes. The result has been the earlier development of the positive reaction which increases in intensity while the indefinite reactions about which there may have been doubts become definitely positive. Completely negative cases are uninfluenced.

CRAIGIE J Application and Control of Ethyl-Ether Water Interface Effects to the Separation of Rickettsiae from Yolk Sac Suspensions. *Canadian J Res. Sect. E. Med. Sci.* 1945 June v 23 No 3 104-14 4 figs. [15 refs]

This paper consists of two parts the first which deals with the use of ethyl ether in the purification of rickettsial suspensions made from infected yolk sacs was issued as a confidential document in February 1942 the second is a supplementary note submitted for publication in January 1945.

Two methods of purifying the triturated yolk-sac suspensions by ether are described. Method A is stated in the supplementary note to remain the

method of choice for the small-scale preparation of pure suspensions of rickettsiae for use in serological investigations whereas Method B which was formerly used in the preparation of vaccines is said to have been replaced later by a method of processing crude yolk sac rickettsial suspensions at pH 7.0

In Method A the triturated suspension is centrifuged the total sediment is suspended in saline buffered with phosphate at pH 7.0 and then emulsified with ethyl ether the rickettsiae are recovered from the aqueous fraction that separates as the unstable emulsion breaks down

In Method B preliminary centrifugation is omitted the separation of the aqueous fraction is controlled by the addition of acetate buffer to the crude triturated yolk sac suspension and there is a maximum yield of rickettsiae which are afterwards treated with ethyl ether

The principles involved and the somewhat complicated technique employed in both methods are described but they cannot usefully be summarized.

The use of ethyl ether in the purification of suspensions of viruses and certain bacteria is discussed in the supplementary note the ether is said to have three useful properties it acts as a bactericidal agent a lipid solvent and a remover of tissue impurities from virus suspensions

BRUMPT L. C & MACLOUF A. C. Un cas de typhus exanthématique à incubation prolongée et apparemment déclenché par un pneumothorax thérapeutique [A Case of Exanthematic Typhus with Prolonged Incubation, and apparently Precipitated by an Artificial Pneumothorax Operation] *Bull et Mém. Soc. Méd. Hôp. de Paris* 1946 Nos. 13/14 205-8.

An attack of typhus fever occurred in a Polish patient who had previously been exposed for a long time to the risk of infection in Buchenwald Camp. Forty-one days before the onset he came into close contact with infected persons and ten days later he was thoroughly disinfested with DDT after having discarded all his prison clothes retaining only his mantle. He reached France 25 days before the onset on arriving in Paris 22 days before the onset he burned all his clothes. Since his disinfection 31 days before the onset he had not been exposed to any known risk of infection.

Artificial pneumothorax was induced seven days before the onset the authors suggest that this may have been responsible for lighting up a latent infection of the reticulo-endothelial system. They consider it unlikely that infection was caused by inhalation of dried infected louse faeces. They mention that the maximum incubation period of louse-borne typhus is stated by DANIELOPOLU as 20 days and by NICOLLE as 22 days also that in murine typhus caused by living vaccine the incubation period may be as long as 25 days.

PROC. ROY. SOC. MED. 1946 Feb. v. 39 No. 4 165-8 (Sect. of Exper. Med. & Therap. 15-18) Discussion on D.D.T. [CAMERON G. R. CHALKE H. D. HILL, K. R. CASE, R. A. M. HELLIER, F. F. HACKETT C. J. CHESTERMAN C. C.]

CHALKE describes the conditions in Naples in the autumn of 1943 which led to an outbreak of typhus in November. During the last five weeks of that year the weekly numbers of cases were 36, 22, 45, 36 and 133. In 1944 up to 9th January the incidence increased to 3-40 a week then dropped dramatically to half this number remained stationary for three weeks after which it fell to 40 early in February then gradually declined there being a total of 1,600 cases.

The main preventive measure applied in the early part of the epidemic was an intensive search for cases and the treatment of all contacts with insecticide

applied in powder form by means of mechanical blowers. Up to the end of 1943 only about 10 per cent. of the dustings were done with DDT the remainder being done with British or American preparations "AL 63" and "MYL," neither of which then contained DDT. From January 1 all dusting was done with 10 per cent DDT in talc and apparently at about the same time the mass dusting of large numbers of people replaced the dusting of known contacts. Chalke concludes that taking into account the incubation period and the fact that few cases were notified before the fourth or fifth day the initial control of the epidemic was brought about as a result of intensive case searching and the ringing of contacts with barriers of insecticide at a time when DDT was used only to a very limited extent. The epidemic, checked in this way was finally ended by the large scale use of DDT.

Chalke also describes the method of use of DDT solutions in the destruction of adult anopheline mosquitoes in Italy in 1944.

HELLIER, describing conditions in Northern Europe mentions a dermatitis associated with purpura amongst soldiers wearing shirts impregnated with DDT and concludes that it was not due to DDT as such but to some associated factor. Presumably as a result of wearing treated shirts, lousiness was very rare among troops in France, Belgium and Holland, though their use did not seem to prevent the occurrence of scabies and pediculosis pubis both of which became common in Belgium and Holland. *G Macdonald*

WOODWARD T. E., PHILIP C. B. & LORANGER, G. L. Endemic Typhus in Manila, Philippine Islands. Report of Cases and Identification of the Murine Rickettsial Agent in Domestic Rats by Complement Fixation. *J Infect. Dis.* 1946 Mar-Apr v 78, No 2 167-72, 1 fig. [10 refs.]

A detailed description is given of an attack of typhus fever in an American soldier which occurred near Manila. *Proteus OX19* was agglutinated at a titre of 1-2,500 the reaction with *Pr OXK* was negative. The murine complement fixation titre rose to 1-384 the epidemic titre was 1-6.

Two other cases were seen in the Manila area, and one in Mindanao though these were not closely studied the serological reactions were of the same type.

Sera of 100 rats (89 of which were *Rattus norvegicus*) caught in Manila, were tested by murine complement-fixation reactions. 18 were positive at titres ranging from 1-12 to 1-192. Only one of the rats reacted with *Proteus OX19* at a titre of 1-80 ten reacted with *Pr OXK* but at low titres of 1-20 or 1-40.

Yenopsylla cheopis in limited numbers, and the mite *Neoschönogaster indica* large numbers were found on the rats.

Suspensions of the brains of two rats and of the mites from another rat, were inoculated into guinea-pigs with negative results. These three rats had given positive reactions with the complement-fixation test. A guinea-pig was inoculated with blood from one of the patients also with negative results.

STUART B. M. & PULLEN R. L. Endemic (Murine) Typhus Fever. Clinical Observations of 180 Cases. *Ann Intern Med.* 1945 Oct v 23 No. 4 520-36 5 figs. [32 refs.]

During the 16 years 1929-1944 180 cases of endemic (murine) typhus were seen in a hospital in New Orleans. Only 21 of the cases occurred during the first ten years of the period. In 1939 there were 16 cases and in the successive five years the figures were —19 44 14 34 and 32. The authors believe that even when allowance is made for better diagnosis there was a real increase in the prevalence of the disease.

The disease was most prevalent in summer and early autumn only two cases occurred in the month of March then the incidence steadily increased, reaching its peak in August in which 49 cases occurred during the five months June to October there were 128 cases the remaining 52 cases were distributed among the other seven months of the year

The average age of the patients was 34.6 years there were no deaths A macular rash was seen in 81.4 per cent of the 129 white patients and in 19.6 per cent of the negro patients it extended to the face in three cases and to the palms in two

The clinical features and Weil Felix responses as described do not appear to differ in any important respect from those commonly observed in louse-borne typhus of corresponding severity

The leucocyte picture was none too characteristic but there was usually a slight degree of leucopenia during the first week and the average total count increased progressively from the fourth day reaching a maximum of 11 000 per cmm by the 15th day Biopsy of the macular lesions was found helpful in diagnosis excised macules were fixed in Regaud's fluid and stained by the Giemsa method.

Although most of the patients were admitted after more than one week's illness the presumptive diagnosis on admission was usually wrong it was typhus fever in only one fourth of the cases

MORALES F H Report of a Case of Typhus Fever *Bol Asoc Med de Puerto Rico* 1946 Feb v 38 No 2 68-9
John W D Megaw

The author describes an interesting case of typhus fever (presumably of murine type) which occurred in Porto Rico in July 1945

The patient had been vaccinated with a Wilmington murine strain of volk sac vaccine about four months previously On July 3 he noticed a purulent discharge from one ear On July 7 he was bitten by a guinea pig suffering from an acute febrile and orchitic reaction after inoculation with typhus rickettsiae On July 12 he was put on a course of penicillin injections for the staphylococcal infection of the ear the treatment was continued till July 22, by which date he had received nearly two million units of the drug On July 20 he began to suffer from a mild attack of typhus fever which lasted 10 days The Weil Felix (O\19) reaction was positive in rising titre which reached 1-3,200 by the 10th day

The attack was attributed probably to the bite of the guinea pig its mildness was thought to have been due to previous inoculation or the penicillin treatment or both combined.

DINGLE DINE Mary J WILLIS Carolyn & HARRELL, G T High Protein Diets in Therapy of Rocky Mountain Spotted Fever *J Amer Dietetic Ass* 1946 May v 22 No 5 389-91
John W D Megaw

Eight children suffering from Rocky Mountain spotted fever were kept on a diet rich in protein carbohydrate and all the vitamins but low in fats When the patients could not be persuaded to take a full standard diet by the mouth gavage was employed

Several children actually gained weight during the illness and the authors believe that convalescence was shortened by the generous diet

No details of the effects of the treatment on protein metabolism are given these are being reported elsewhere.

YELLOW FEVER.

LAGOS NIGERIA. Annual Report of the Yellow Fever Research Institute 1945. 110 typed pp 12 photographs 5 maps 12 figs. & 1 folding chart.

The Annual Report of this Institute for 1944 was reviewed in this Bulletin 1945 v 42 800. The Institute was reopened for full work towards the end of 1943 after an interval of almost 10 years during which it had practically been closed and during 1944 most of the work done was preliminary to the projected full-scale activities which were envisaged for the future. During 1945 the staff was built up and in the last quarter the Institute functioned with a full staff for the first time. New buildings were constructed, but it was not possible to erect permanent structures.

One of the first enquiries made was an investigation of the distribution of yellow fever in Nigeria. Only one case had been found since 1942. Protection tests were carried out on blood from the people especially children from various parts of the country and the results showed 16 per cent. of positive tests. Immune children were found relatively frequently in areas in which the disease has been reported during the last 10 years but the most interesting discovery was that, according to this evidence there had been a recent outbreak of appreciable proportions within sight of Lagos. Moreover three monkeys shot in the vicinity all gave strongly positive tests. Lagos itself, however appears to have escaped, and the explanation of this is not certain. It may be that the relatively low density of *Aedes aegypti* would not permit an extensive outbreak, or that the strain of *Aedes aegypti* present is poor in carrying power. The information however indicates repeated widespread yellow fever outbreaks among the Africans throughout Nigeria south of latitude 10° N. It is calculated that there must have been many thousands if not several hundreds of thousands of cases in the past 15 years yet recognition of the disease in the Africans is exceptional. Part of the explanation no doubt is that the medical service is inevitably thinly spread over the country but more important is the fact that in the African yellow fever tends to be a mild disease. This is not true of Europeans and the absence of large outbreaks in Europeans must be attributed to preventive measures, of which vaccination is the chief. As a background to the human disease there lies the still almost unknown subject of yellow fever in monkeys. Evidence has been collected which points to these animals as the reservoir but the subject has not yet sufficiently been studied. Investigations are now being made.

The experimental work done at the Institute included a study of the susceptibility of mice of different ages to subcutaneous injection of yellow fever virus. In the course of this study it was found that there is marked change in the blood-brain barrier. This change can be detected at the 7th day of life and develops with great rapidity to the 10th day. In other words before the 7th day a relatively small dose of virus given subcutaneously will kill the mice after the 10th day the dose must be many thousands of times greater to achieve the same result. This phenomenon is probably due to the fact that mice are born while still in a relatively embryonic state. It seems not to be true of guinea-pigs which are more mature at birth. The practical outcome of this and similar work in South America is that for the mouse-protection test, animals less than 8 days old should be used, and small amounts of virus. In this way weakly positive sera which with grosser tests would be missed, can be detected.

The susceptibility of mice to the yellow fever virus has been very thoroughly investigated. Two strains of mice are kept at the Institute one from Lagos (originally from Hamburg) and the other from Entebbe (originally from Rio

de Janeiro) In each strain there exists a fraction which for all practical purposes is completely resistant to the virus in the Lagos strain about 7 per cent and in the Entebbe strain about 1 per cent of the mice appear to be refractory These qualities of susceptibility or non susceptibility appear to be genetic and work has now been put in hand whereby by selective breeding it is hoped to rear a susceptible strain from the Entebbe strain. An interesting fact has been observed namely that mammary carcinoma develops very frequently in the Entebbe strain but not in the Lagos strain

On the basis of the finding of susceptible strains of mice the argument is developed that the same phenomenon probably occurs in other wild animals in nature and that certain strains of mosquitoes (for instance *Aedes aegypti*) may not possess the faculty of transmission of the virus to the same extent as other strains For instance, *Galago demidovi* (the smallest of the bush-babies) was found to be somewhat refractory to yellow fever virus though the larger species *G. senegalensis* was found by Smithburn in East Africa to be highly susceptible Investigations into the vector efficiency of varieties of *Aedes aegypti* are being made and the evidence is becoming more conclusive that populations of the same taxonomic group may differ markedly in their response to virus and that these variations may exist in the same area at different times Inevitably epidemiology develops genetic facets for complete understanding [This important subject of inherited characters has a very wide application not only to the susceptibility of hosts to an infecting organism, but also probably to the infective power of different strains of the infecting organism. It is discussed in relation to trypanosomes by CORSON (this *Bulletin* 1946 v 43 169-176) and the work of LURIE on susceptibility of in-bred strains of rabbits to the tubercle bacillus is also much to the point (see *Bulletin of Hygiene* 1941 v 16 670 1945 v 20 313) The development of similar enquiries may lead to extensive changes in the conceptions of epidemiology.]

Other laboratory investigations included the estimation of the effect of temperature on the virus-antibody reaction tests of susceptibility of local guineapigs the effect of defibrination and of sodium citrate on virus in blood (these are not deleterious to the virus) and the effect of variations in the time of injection of starch into the brain in relation to intraperitoneal injection of virus (simultaneous injection of each appears, on the whole, to be the best procedure)

It is well known that the development of a viscerotomy service is essential to the efficiency of a research and control scheme for yellow fever The beginnings of such a service have now been made in Nigeria. Difficulties are expected, especially among the Mohammedans of the north but elsewhere it seems to be quite possible that viscerotomy will be successfully carried out

Some work was carried out on other diseases in which the suspicion was aroused that they may have been due to viruses other than that of yellow fever but without definite result. An account is given of the distribution of yellow fever vaccine during the year

Charles Wilcocks

HEATON C E. Yellow Fever in New York City *Bull Med Library Ass.* 1946 Apr v 34 No. 2, 67-78 [38 refs.]

A historical account.

FREEMAN G. Epidemiology and Incubation Period of Jaundice following Yellow Fever Vaccination. *Amer J Trop Med* 1946 Jan., v 26 No. 1 15-32, 8 figs. [14 refs.]

An epidemiological study of jaundice following yellow fever vaccination was undertaken at Camp Baker in the south-eastern U.S. About

half of the population of 18 000 was transient moving in and out on a weekly schedule while the other half was permanent and could be more clearly studied. The epidemic coincided in time and duration with the large general epidemic among American troops during 1942. Altogether slightly more than 700 cases or approximately 3.8 per cent. of the total average population at risk, were hospitalized with jaundice. The first six cases occurred sporadically between August 1941 and February 1942 and these patients had not been vaccinated. Three companies were inoculated on December 30th 1941 and during the first week of January 1942 and of these approximately 500 men nine had jaundice during the last 3 weeks of March or roughly 70-80 days later. The three companies were housed in nine barracks holding some 50 men each: no cases occurred in 7 of the barracks, 4 in one and 5 in another: a distribution very unlikely to occur by chance. The bulk of the population was vaccinated between February 23rd and March 9th 1942 and the main epidemic was continuous from May to September with its peak in the last week of June. The personnel first affected belonged to Company A of Regiment Z. Members of this Company had received either YFV lot M1 or M2 during the first week of March while at the same time the rest of the regiment received M2. 13 cases occurred in Company A during May and the first week of June before any occurred in the remainder of the regiment: an event most unlikely to occur by chance. The spatial distribution was also odd, for of the 12 barracks in which Company A was housed 9 had no cases, 1 had 1 case, 1 had 3 cases and 1 had 7. Examples from other units are given of these discrepant events both in space and time.

The average interval of time between vaccination and onset of epidemic jaundice was 12.3 weeks but varied between units from 11 to 15 weeks. The incidence in units appeared to fall in defined waves with an interval of 2 to 4 weeks between their peaks and an average of 3.2 weeks.

It appears therefore that there were two factors interwoven in this epidemiological pattern: namely YFV and the focal grouping of cases. The latter the spatial and temporal grouping of cases of jaundice in certain barracks and units among troops having received common YFV at approximately the same time points towards a communicable disease with an incubation period of 2-4 weeks rather than to one caused by iatrogenic vaccine. A large increase in the attack rate on the unvaccinated population was also observed and it is likely that all the cases of jaundice whether they did or did not receive YFV had a common aetiology. The YFV used on certain Army posts appears to have had the property of predisposing its recipients to the communicable disease referred to as jaundice and this property varied among the several lots of YFV.

[The evidence is set out graphically and the paper is a difficult one either to read or to abstract adequately.]

PLAGUE

BRATNAGAR, S. S. & SHRIVASTAVA, D. L. An Experimental Study on Cellular Immunity in *Pasteurella pestis* Infection. *J Hygiene* 1948 May v 44 No. 5 307-13 3 coloured figs. on 1 pl. [20 refs.]

This study relates mainly to the leucocyte picture of the peripheral blood as an index of resistance or immunity. A supravital staining technique was

used with neutral red as the indicator stain. Janus green the mitochondrial stain which is ordinarily used along with neutral red, had to be omitted as the combination of the stains was too toxic for cells in the presence of a bacterial infection. Total leucocyte counts and differential counts were also used. The two test animals were the highly immune Bombay rat and the highly susceptible inbred laboratory mouse. Immunization (passive) or protection was effected by injection of one of the three types of sera known as pure envelope, pure somatic and whole antiplague serum. Of the pure sera it is the envelope type alone which is protective and this was confirmed by the cellular leucocyte response here investigated. Two types of leucocyte or rather three are distinguished the polymorphonuclear (or microphage) and the macrophages (monocyte and clasmatocyte). Clasmatocytes are distinguished from monocytes by their much greater size and were significantly absent during the tests of cellular response in relation to active immunity of susceptible mice. Here the polymorphonuclear leucocyte reacted vigorously at an early stage and it was this cell which appeared to form the first and the last line of defence of the susceptible inbred laboratory mouse. Its steady deterioration cytologically was an index of the downhill course of infection.

It was otherwise with the cellular response to the protective envelope serum where the penetration and segregation in pattern of neutral red was a marked index of immunity. No protective value of polymorph leucocytosis could be demonstrated in either serum treated or non treated white mice. It was the detection of clasmatocytes in the peripheral blood that was found to be an objective observation of great prognostic value and this has to be coupled with observations on the monocytes. The association of monocytes with passive protection was well marked. Their maintenance at high level connoted protection while a significant diminution in their number heralded a fatal termination. An increase or a decrease of neutral red vacuoles in monocytes or clasmatocytes was an indication of degree of functional digestive activity for living particulate material. It was this index which was found both in the case of immunity and susceptibility to show whether the struggle was developing in favour of host or parasite. The test should therefore as the authors contend be valuable for immunological assessment of the value of plague-serum therapy and plague prophylaxis.

BACILLARY DYSENTERY

BRODIE J COOK R P DRYSDALE Constance F & McINTOSH D G Treatment of Sonne III Bacillary Dysentery and Bacillary Dysentery ("Clinical") with Phthalyl Sulphathiazole *Brit Med J* 1946 June 22 948-50 [10 refs.]

Forty-eight cases of Sonne III dysentery and 40 cases of clinical dysentery (blood and mucus in the stools but no organism isolated) were treated with phthalyl sulphathiazole at King's Cross Hospital Dundee in the period from August 1944 to June 1945. The dosage is shown in Table 1.

TABLE I.
Dosage of Phthalyl Sulphathiazole

Age in years	Grammes per day					Total in grammes
	1st	2nd	3rd	4th	5th	
0-2	3	1	1	1	1	7
3-5	5	2	2	2	2	13
5-12	10	3	3	3	3	22
Over 12	15	4	4	4	4	31

The results are compared with those obtained by JAMIESON, BRODIE and STIVER [this *Bulletin* 1944 v 41 754] who treated 100 cases with sulphaguandine 50 with saline aperients and 50 with chalk mixture this comparison is shown in Table III.

TABLE III
Comparison of Treatments for Bacillary Dysentery

Treatment	No. of cases		Average time in days required for clinical cure		Cases positive bacteriologically in convalescence			
	Sonne III	Total	Sonne III	Total	Sonne III		Total	
					No.	%	No.	%
Aperients	11	50	6.3	6.5	4	36.4	25	50
Chalk	18	50	7.6	6.0	11	61.1	26	52
Sulphaguandine	10	100	4.7	5.0	4	40.0	30	30
Phthalyl sulphathiazole	48	—	8.73	—	10	20.8	—	—

The present results with phthalyl sulphathiazole agreed with those obtained with sulphapyridine by STIVER [this *Bulletin* 1943 v 40 844] who found that the stools in treated cases remained abnormal for 9 days compared with 20 days in control cases.

The amount of free phthalyl sulphathiazole in faeces, blood and urine was estimated and it was shown that a small amount had been absorbed from the alimentary canal.

In vitro experiments showed that phthalyl sulphathiazole exerts a bacteriostatic effect against a number of intestinal organisms. A Flexner strain a Sonne III organism and a strain of *B. coli* were completely inhibited in semi-solid and fluid media containing the drug.

The authors conclude that phthalyl sulphathiazole did not influence the clinical course of Sonne III dysentery but reduced considerably the number of cases bacteriologically positive in convalescence.

J. F. Corson

AMOEBIASIS AND INTESTINAL PROTOZOAL INFECTIONS

DORMER, B A *Pulmonary Amoebiasis. Proc Transvaal Mine Med Officers Ass* 1945 Nov 1 25 No 278 113-27 6 diagrams & 23 pls

In Natal S Africa, acute amoebic dysentery and amoebic hepatitis are very rare in the well fed Europeans although 5 per cent. harbour *E histolytica* they are also very uncommon in the fairly well fed Indian population but they are very common in the Bantus 17 per cent of whom have been shown on a single stool examination to harbour the parasite (three times this number may therefore be assumed to be infected) The incidence of acute and of metastatic *E histolytica* infections in the Bantus has risen steadily since the war especially in the urban areas Tuberculosis and amoebiasis show a strange parallelism in the Africans who are poorly fed and live on a protein-deficient diet. The author postulates that a high carbohydrate (especially maize or rice) and low animal protein diet favours amoebic bowel infection and that a reasonably high protein diet with wheat as the staple carbohydrate does not do so The stools of the African are highly acid indicating a bacterial chemical and physical state of the bowel favourable to amoebiasis while those of the European are alkaline and the conditions are unfavourable to the parasites [No explanation is offered of the low incidence of amoebiasis and its manifestations in the presumably rice-eating Indian community] Epidemic bacillary dysentery is rare in the Natal native and this is due to the acid bowel medium which does not favour the growth of the causative organisms.

Amoebiasis is common in the tropics as high relative humidity leads to longer survival of cysts outside the body and the food habits of the people are conducive to its establishment in them Infection rates on the coast are greater than inland as inland the humidity is less and the temperature lower The author considers that the provision of adequate first-class protein in the diet of the Bantus and the reduction of maize and rice products as the principal source of carbohydrate with replacement by wheat would with proper sanitation and education control the situation. The treatment of the individual essentially consists of dietary rectification with drug treatment as an ancillary where necessary The author then goes on to a discussion of pulmonary amoebiasis illustrating by drawings and X ray photographs cases of direct extension of infection from the liver to the lung and of embolic infection of the lung

[The author's conclusion that diet *per se* plays a major part in the infection of the individual does not appear to have been substantiated elsewhere In the Japanese prison camps amoebiasis was very prevalent and almost exclusively rice diet Furthermore amoebiasis was not unduly obtrusive when living on a high protein diet under the unavoidably insanitary fly ridden conditions obtaining for brief periods during active operations. Again while high relative humidity may favour longevity of cysts outside the body high temperatures do not do so and cysts will not withstand ordinary drying whatever the atmospheric humidity Does not a more adequate explanation of the incidence of amoebiasis lie in the personal habits housing and sanitary standards obtaining among the various communities?]

CHAUDHURI R N & RAI CHAUDHURI M N *Pulmonary Amoebiasis. Indian Med Gaz* 1946 Feb 1 81 No 2 66-7 3 figs. (1 on pl.)

A R D Adams

Amoebiasis of the lung is much more common than is thought but is often undetected, or is misdiagnosed as pulmonary tuberculosis The authors review some of the few published reports of the clinical condition and add to these

two further case reports from the Carmichael Hospital for Tropical Diseases Calcutta. Both patients were Bengali women aged 24 years. In the first case the X-ray appearances were suggestive of tuberculosis but no bacilli were found no *E. histolytica* were recovered from the sputum or stools and emetine injections cured the pain and physical signs in the right chest, the cough, fever and loss of condition for which the patient was admitted. In the second case *E. histolytica* but no tubercle bacilli were found in the sputum and none in the stools on admission to hospital there were fever cough, and blood-stained sputum but no physical signs and again, emetine injections proved specific. Both cases had some leucocytosis that in the first being marked (23,500 per cmm.) and that in the second slight. In each case there was initial aggravation of the symptoms on beginning emetine injections. A R D Adams

WITHERSPOON F G Exfoliative Dermatitis associated with Amoebic Dysentery *Arch Dermat & Syph* 1946 Mar v 53 No. 5 506-7

A case of exfoliative dermatitis with an associated amoebic dysentery is described. On successful treatment of the amoebic infection great improvement in the dermatologic condition occurred. A search of the available literature has revealed no similar case.

CHAPIN S. E. Positive Urine Methylene Blue Test in Amoebic Hepatitis. *J Amer Med Ass* 1946 Apr 20 v 130 No 16 1071-2.

In a case of amoebic hepatitis in a young American Marine the methylene blue test of the urine see *Bulletin of Hygiene* 1945 v 20 660] was strongly positive and the urine contained a considerable amount of bile. *Entamoeba histolytica* was present in the faeces in large numbers. Treatment with emetine, carbarsone, choline chloride a high protein diet and multivitamin tablets was followed by apparent cure in 3 weeks. The methylene blue test of the urine became negative on the 5th day after the beginning of treatment.

The authors recommend the test as directing attention to the liver in acute inflammations of that organ. J F Corson

CHAUDHURI R. N. & RAI CHAUDHURI M. N. A Case of "Amoeboma." *Indian Med. Gaz* 1946 Mar 81 No 3 138-9 3 figs. on pl.

HARGREAVES W. H. The Treatment of Amoebiasis with special reference to Chronic Amoebic Dysentery *Quart. J Med* 1946 Jan., v 15 No 57 1-23. '85 refs.]

After a brief account of the distribution, epidemiology and incidence of amoebic dysentery the author reviews in detail the drugs believed to exert some influence on the infection. Emetine is the most effective drug available but alone, it is not often curative. Emetine bismuth iodide is the most efficient basis for combined specific treatment if it is given in a proper form as a powder in gelatin capsules and not in pills or tablets. After stressing the importance of early diagnosis and efficient treatment the author discusses the bewildering number of treatments variously advocated, and the criteria by which their efficacy has been judged. The variations in the claimed successes of various treatments by sundry authors may be attributable to variation in the standards adopted for assessment of cure. The pathology of the infection in the bowel and the symptomatology due to it receive attention at some

length and the author then turns to the refractory cases of amoebic dysentery which arrived in the United Kingdom from the Far Eastern theatres of the late war. Questions of emetine-resistance of variations in virulence of different strains of parasites and of secondary bacterial infection superimposed on the amoebic infection are considered in detail. Hargreaves does not think there is any evidence of the development of emetine fastness by *E. histolytica* and the position in regard to variations in virulence of different strains of the parasite he thinks is far from clear. The available evidence points to differences in susceptibility of the patients rather than to biological differences in the strains of organisms as the cause of variations in severity of the manifestations resultant on the presence of the parasite.

Secondary bacterial infection plays an important part in determining the severity of the colitis and in preventing a satisfactory response to anti amoebic treatment. Successful control of this secondary bacterial infection with penicillin and succinyl sulphathiazole results in markedly more effective action of the amoebicidal drugs and it also may save life in grave cases of superadded bacillary colitis. Chronic cases of amoebic dysentery previously labelled emetine-resistant have been cleared of their infection by standard treatment with EBI and chiniofon enemata after a penicillin and sulphasuxidine course. Only occasionally has more than one course of the standard anti-amoebic treatment been necessary to obtain cure after the bacterial infection has been dealt with although this latter may need more than one course of penicillin and sulphasuxidine to overcome it.

The indications for surgery in amoebiasis and the use of the sigmoidoscope are discussed and the general management of the patient and the author's standards of examination for cure are detailed. That the difficulties in the diagnosis and treatment of amoebiasis were fully realized by the Germans is evident from the fact that they dropped propaganda leaflets containing advice to our troops on the methods of simulating the disease in its refractory form. A copy of one of these is given.

WANTOCH H G Zur Frage der sogenannten nicht-pathogenen Amöben.
[So-called Non-pathogenic Amoebae.] *Schweiz. med. Woch.* 1946 Mar
30 v 76 No 13 280-81

The author from his experiences in Shanghai maintains that the so called non pathogenic amoebae of the human intestine are far from being non-pathogenic for in his experience they are liable to cause various disturbances such as abdominal discomfort or pain diarrhoea or constipation. In no case, however is there real dysentery with blood and mucus in the stools as in the case of *E. histolytica* infections. In most of the cases quoted *E. coli* was the amoeba present and when the infection was eradicated by yatren acetarsol carbarsone or other suitable remedies the symptoms abated.

C M Wenyon

RELAPSING FEVER AND OTHER SPIROCHAETOSSES

WILLIAMSON J & LOURIE E M Therapeutic Action of Different Penicillins
on *Spirochaeta recurrentis* Infections in Mice *Brit. Med. J.* 1946
June 1 828-9 [11 refs.]

The authors have compared the therapeutic action of three different preparations of penicillin—(a) The partially purified product as issued for

parenteral injection (b) crystalline penicillin II (c) crystalline penicillin III—on relapsing fever infections in mice.

No significant differences were found between the actions of the partially purified preparations and crystalline penicillin II but penicillin III was substantially less effective.

The present experiments suggest that it is becoming increasingly necessary to investigate the anti-spirochaetal properties of the by-products in the manufacture of penicillin. Since the more easily and more copiously produced forms of penicillin such as penicillin II are more active against infections of *Spirochaeta recurrentis* it is suggested that they may also be more active against *syphilis*. This would be fortunate if substantiated, since this disease requires such a high aggregate dosage.

AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE. PUBLICATION No. 18. A Symposium on Relapsing Fever in the Americas.

This book is reviewed on p. 881

NOBREGA, G. Um caso de sodoku [A Case of Bat Bite Fever] *Brasil Medico*. 1946 Feb. 2 & 9 v. 60 Nos. 5/6 35-8 2 figs.

Up to April 1939 Professor DA FONSECA had recorded 14 cases of sodoku in Brazil. Nevertheless, says the author none of the standard text books on tropical medicine contains any reference to the existence of this disease in Brazil [but SITTI mentions South America in the geographical distribution]. The author consequently is anxious to place the present case on record.

The patient was a boy of 11 years and was bitten on the left hypothernar region on 23rd September 1943. The wound bled slightly and was treated with mercurochrome. Four days later the wound became painful and there was a little discharge from it. Six days after the bite he had a bout of fever and the wound continued to be painful. It then healed and cicatrized but during the next 3 weeks he had 5 paroxysms of fever lasting for 48 to 72 hours. They were not ushered in with any rigor or shivering and there was no terminal sweating—the only symptoms were the rise of temperature to 39.4°C., with headache and rapid pulse. The epitrochlear gland was swollen and slight enlargement of the axillary glands was observed. *Ascaris* and ankylostome ova were numerous in the faeces but there was no eosinophilia (4 and 3 per cent. only on two occasions when the total leucocytes were 13,500 and 16,000 per cmm.) As the wound had healed no fluid could be obtained from it for examination. Gland puncture was refused, but 15 cc. of blood taken during a febrile paroxysm was inoculated into white rats (camondongos) and these animals 11 days later showed infection by *Spirillum minus*.

LEPROSY

SCHUYLMAN, S. Criterio para otorgar el alta hospitalaria a los enfermos de lepra. [Criteria for the Release of Leprosy Patients from Hospital.] *Rev. Argentina Dermatofilologia* 1945 Dec. v. 29 No. 4 249-52.

One gathers from the text of this article that the subject of discharge of lepers from hospital was posed as one for discussion at the Third Congress on Leprosy. The term "discharge" is regarded as being of three types: (1) Permission to leave hospital on the promise of continuing treatment and attending a dispensary. (2) Conditional on coming up periodically for observation.

(3) Definitive the patient ceasing treatment and severing all connexion with the Leprosy Department. The present contribution deals with the first of these. It is of epidemiological importance from the points of view of the patient his relatives and associates.

Rules at present are far from uniform. In the Philippines it was the custom to let the patients go from hospital after being for 6 months bacterially and clinically negative but a large percentage were found to relapse so the time was increased to one year. In Hawaii patients were let out on parole after three negative examinations carried out at intervals of 3 months. At Carville when a patient became negative he was passed on to a special section of the establishment where he was treated and under further control for two years and if at the end of that time he was still negative he received his discharge. In São Paulo they used to be released after being negative for a year but so many were found to relapse that this period was doubled.

In the author's view the decision must depend on several grounds. It is of the utmost importance to note the condition on arrival the type and extent of the disease. Notes on progress must be made frequently and discharge from hospital will depend on the clinical state on admission the number of bacilli then present and on the progress made clinically and bacterially and immunologically and on the treatment which has been adopted. With this proviso he suggests the following as guides.

- (a) *Tuberculoid cases* with isolated lesions may be allowed to leave after being bacterially negative for 8 months. For those showing reactions the time should be prolonged to a year in those giving a definitely positive Mitsuda test and 1½ years in those giving a weak positive.
- (b) In *lepromatous cases* we should be more cautious according to the intensity of the process. Those of L1 type should be detained in hospital for two years after they become negative. Treatment should be continued during this time and frequent clinical and bacteriological examinations should be made bimonthly for the first year and monthly for the second. For L2 and L3 patients the period should be at least three years and provocative measures should be tried such as the giving of potassium iodide sulphanilamides tuberculin etc. before a case is declared negative.

CERBONI E. A. PECORARO V. & RODOLFO MERCAU A. Bases para la reglamentación de las altas de los enfermos de lepra. [Bases for Rules for Discharge of Lepers from Hospital.] *Rev. Argentina Dermatosisifilogia* 1945 Dec. v 29 No 4 253-6

The rules or regulations proposed by the authors are based on those of São Paulo adapted to the South American classification of cases of leprosy and to the present-day ideas on its immunology. A brief sketch of what is done in other countries is given as a preliminary. [These have been noted in the preceding abstract and need not be repeated.] The rules are laid down for the three types mentioned by SCHUJMAN [see above.]

1. *Release from In-patient Treatment*—(1) Within 30 days of admission the patient should be examined and classified in one of the following three categories (a) Lepromatous (b) Non-characteristic, bacteriologically positive (c) Tuberculoid bacteriologically positive.
- (2) When they become bacterially negative. Those of (a) should continue under observation for two years those of (b) who react negatively to immunological tests to be under observation for 12 months those positively reacting for 6 months those of (c) to be kept under observation for 6 months.
- (3) During the period of observation they should undergo a clinical and bacteriological examination (the latter of the skin the nasal mucosa and gland

juice obtained by puncture) every 3 months and a histo-pathological examination every 6 months.

(4) The above being satisfactory an ophthalmological and laryngological examination should be made to exclude any active lesions in these sites.

(5) The patient is then sent, with his clinical history before a medical board. In addition to the history of the case from the time of the patient's admission, information should be furnished regarding his intended place of residence, his means of living and his immediate associates will be under supervision.

(6) A patient so discharged should subject himself for re-examination every 4 months for 2 years and bring a certificate from his doctor that he has been under his constant treatment.

The patient will now come under the category of those —

II *Conditionally discharged* with permission to engage in certain occupations and to suspend treatment with the doctor's consent. The following may come under this heading: Tuberculous cases and the non-characteristic bacterially negative, which have had two years' treatment whose lesions have retrogressed and who show no signs of activity.

Patients conditionally discharged are still under observation by the Board and should be examined every 6 months for 5 years being treated or suspending treatment at the decision of the medical attendant.

III *Definitive discharge*—Those who have fulfilled the conditions of the previous group—who have been examined every 6 months for 5 years have remained clinically free from symptoms and bacterially negative even after provocative tests as by administration of potassium iodide and any other tests which the Board may require—will be eligible for final discharge.

H Harold Scott

FLOZ, H. *Altas a los enfermos de lepra.* [Discharge of Lepers from Hospital.] *Rev Argentina Dermatossifilologia.* 1945 Dec. v 29 No. 4 257-62. [10 refs.]

Some nations, the Japanese for example believe leprosy to be incurable and therefore have no rules for discharge of patients. The author starts by stating the criteria of cure and calling for consideration of the following points. Absence of any clinical signs of activity absence of lepra bacilli from the nasal mucosa, of active lesions of the skin, nerves or glands and absence of signs by biopsy by biological tests and provocation tests (as the giving of potassium iodide) and Fernandez's test the subcutaneous injection of lepromin.

The advantages of discharging patients are that the outlook of all is brightened, the morale of those remaining is raised by their realizing the possibility of their own discharge inciting other patients to enter hospital in search of cure and reducing congestion of leper colonies. Its drawbacks are the need for keeping an eye on and exercising control over those liberated, watching for the first signs of relapse indiscipline among the discharged failure to attend for examination, changing residence and so on.

The author next gives figures quoted from the literature, to illustrate the frequency of relapsing cases and shows that the returns are very varied. HAYASHI gives the rate as high as 50 per cent., DENNEY as low as 3 per cent. CAMPOS gives 17.4 but the figure depends much on the type of disease—lepromatous cases 5 per cent mixed 38 maculo-anaesthetic 12.0 per cent. and so on.

Definitive discharge he suggests, should not be absolute but should be subject to annual revision. The rest of this article is taken up with what is done elsewhere as at S. Paulo and the criteria mentioned in the foregoing abstracts.

H Harold Scott.

- GARZÓN R. & ARGÜELLO PITT L. Conveniencia de unificar el criterio y la reglamentación de las altas en los enfermos de lepra. [Convenience of Unifying the Rules for Discharge of Lepers from Hospital.] *Rev Argentina Dermatofilologia* 1945 Dec. v 29 No 4 263-5

This covers much the same ground as the preceding abstracts. The authors stress the fact that everything depends on the type of disease, the frequency of examination the constant vigilance to discover the earliest signs of relapse be provisional discharge with constant observation and frequent re-examination before the final free release is granted.

H Harold Scott

- ARGÜELLO PITT L. & CONEJOS M. La bacteriología de la lepra tuberculoides [Bacteriology of Tuberculoid Leprosy] *Rev Argentina Dermatofilologia* 1945 Dec. v 29 No 4 909-11

In the Leprosy Congress at Cairo in 1938 the decision was reached that tuberculoid leprosy was not a fundamental form but merely a variety of the neural type. In the following year however at Brazil, the Congress decided that it was a fundamental form with characteristic histological changes. Epidemiologically it differed from the lepromatous in not containing bacilli and so was practically non-contagious. Others have maintained that the lesions may transitively contain bacilli for days at a time perhaps for months.

To determine whether these lesions were bacilliferous or not the authors have examined 78 cases. BICHELLI in 1940 found 84 positive among 466 cases (18 per cent). FERNANDEZ in 1939 found 12 positive among 14 but all were in a reaction state. Among the authors 78 typically tuberculoid cases they found bacilli in 8 six were in a reaction state two were not.

- SPRECHER, A. Alterazioni patologiche delle ossa nella lebbra. [Bone Pathological Changes in Leprosy] *Pathologica* 1940 Apr. v 32 No 582 133-48 15 figs [24 refs] English summary

The author studies radiologically the pathological changes of the distal bones in twenty lepers with disease of various forms and in various evolution stages. He discusses the radiological findings obtained and reports a first brief histological pathological examination.

- OLMOS CASTRO N. & BONATTI A. A. Acerca de la propiedad floculante de los sueros leprosoes [Flocculation of the Serum in Leprosy] *Rev Argentina Dermatofilologia* 1945 Dec. v 29 No 4 290-300 2 graphs. [25 refs]

This is a study of the precipitating property of the sera of lepers when in contact with a certain antigen and of the physico-chemical factors concerned, with a view to devising a method of sero-diagnosis of leprosy.

The antigen is obtained by boiling a leproma nodule in water for half an hour cutting it in small pieces, brazing to a smooth paste in a mortar adding chloroform little by little evaporating this in a water-bath to obtain a residue of bacilli and lipoids. Sulphuric ether is added and the bacilli are separated by centrifuging. The supernatant fluid, rich in lipoids is evaporated in a porcelain capsule and the residue dissolved in 100 times its volume of 95 per cent alcohol. After being left for two days it contains a small residue and an amber-coloured supernatant fluid which is the antigen. About 0.05 gm. of

treatment by intramuscular and subcutaneous injections of chaulmoogra (which often say the authors makes matters worse) and by protein shock milk calcium autohaemotherapy and other methods the authors give an account of their own investigations into the use of intravenous injections of benzylic esters of chaulmoogra (Neochaalmestrol)

The mode of administration was intravenously drop by drop starting with 0.5 cc. and repeating every 4-7 days and increasing the dose according to tolerance. The patients selected were lepromatous cases with ocular lesions which had proved refractory to the forms of treatment mentioned above. For small doses up to 3 cc. an ordinary hypodermic syringe was used injections being made slowly 1 cc. in 8-10 minutes. In most cases marked improvement followed weekly injections of 1.5-2 cc. In some cases a dosage as high as 10 and even 12 cc. at each session has been attained. The only untoward symptoms have been cough retrosternal oppression and dyspnoea.

The immediate results have been distinctly encouraging, for with the usual chaulmoogra treatment the eye symptoms may be aggravated and treatment consequently has to be stopped. With the new treatment the severe pain in the eyes associated with the ocular complications of leprosy disappears together with the photophobia, lachrymation and corneal oedema. Some of the good, it is thought may be due to pyretotherapy for the injections cause a rise of temperature to 38-39 C. with small doses to 40 and lasting longer with larger doses. The authors acknowledge that the method is only on trial but they put it forward in order that others may test it also.

Brief notes are given of 20 patients so treated the total dosage ranging up to 63.5 cc. and the duration of treatment up to 7 months. All improved some very early in the course and say the authors this drug seems to be the most efficacious of all those hitherto employed in the acute ocular complications of leprosy.

BLANCO J F Alcoholización del ganglio ciliar [Alcohol Injection of the Ciliary Ganglion (In Leprosy)] *Rev Argentina Dermatofilologia* 1945 Dec. v 29 No 4 275-7

Injection of alcohol into the ciliary or ophthalmic ganglion is recommended for relief of the ocular pains of leprosy. For preliminary anaesthesia the author injects at a depth of 4 cm. along the outer wall of the orbit and directed upwards 1 cc. of adrenovocaine (1 per cent novocaine with one drop of 1 per cent adrenaline) and follows this with 1 cc. of alcohol 60 degrees [presumably 60 per cent]. The consequent palpebral oedema, slight exophthalmos and subconjunctival ecchymosis subside in a few hours. In many lepers the ocular lesions—parenchymatous keratitis secondary to chronic irido-cyclitis atrophy of the iris syneciae pupillary occlusion repeated silentis secondary glaucoma etc.—render the eye practically functionless.

Six cases are detailed all adults with advanced leprosy and severe eye symptoms as mentioned above and all within a few days were much relieved the pain photophobia and lachrymation disappeared. Moreover the effect was lasting the patients were seen periodically and six months after the injection the improvement was still maintained.

GUADAGNINI M Tratamiento de las úlceras leprosas por la novocaína endoarterial. [Intra-arterial Novocaine in the Treatment of Leprous Ulcers.] *Rev Argentina Dermatofilologia* 1945 Dec. v 29 No 4 278-82 2 figs.

The author is dealing with leprosy ulcers of neural origin in which the actual ulceration is preceded by bullae with serous or sero-purulent content superficial at first but later extending to the deeper tissues and in some cases producing the

typical perforating ulcer. They are commonest about the ankles and in the soles. The author's method of treatment from which he reports good results, is to inject 20 cc. of 2 per cent. novocaine into the femoral artery slowly, taking 3-4 minutes over the injection. A feeling of heat is produced, which persists for 1-2 hours with rapid alleviation of the pain and ease of movement of the limb. The patient should rest for a few minutes to avoid the sensation of nausea from the novocaine. Injections may be given twice or thrice weekly.

TURANGUI M. A. Preliminary Notes on the Crustacean Vector of the Mammalian Lung Fluke (*Paragonimus*) in the Philippines. *J Parasitology* 1946 Apr., v 32, No. 2 150-51.

Infestation by *Paragonimus* has been known in the Philippines for close on 40 years. MUSGRAVE having reported a case in 1907. It is however not widespread, but confined to certain localities. In 1941 snails (mostly *Udania*) crabs (*Polamon*) and prawns (*Palamon* sp.) were collected and examined. The first and last proved negative but of 216 crabs, 60 per cent. were found to be harbouring up to 50 cysts most in the leg muscles others in the gills, liver and thoracic muscles. Rats and cats fed on these developed adult *Paragonimus*. These crabs are eaten uncooked by the people, after removal of the legs, carapace and gills, or after shaking them with salt and keeping them for 24 hours. The metacercariae in the leg muscles were found to be still alive and infective for 7 hours after such treatment but not after 24 hours. If merely immersed in water they were still alive after 4 days. Sometimes the crabs are eaten uncooked after immersion in vinegar with a little salt in these circumstances the metacercariae were still alive 4 hours later and infective. The molluscan host has yet to be discovered.

SUBRAHMANYAM, R. Somatic Tasmiasis (Solium Cysticercosis) *Indian Med. Gaz* 1946, Feb. v 81 No. 2, 64-5 3 figs on 1 pl.

COGGESHALL, L. T. Filariasis in the Serviceman. Retrospect and Prospect. *J Amer Med. Ass.* 1946 May 4 v 131 No. 1 8-12.

Many doctors in the United States will encounter filariasis for the first time on the demobilization of several thousand servicemen infected with *Wuchereria*

bancrofti during the war. The future of these men and the risk of secondary infection of others are matters of current importance. Bancroftian filariasis was common in the United States particularly some of the Southern States during the days of slave importation but when these ended the disease was unable to maintain itself and gradually diminished finally disappearing in 1925. A similar introduction and temporary lodgement occurred in Australia. At one time 10 per cent of all persons hospitalized in Brisbane suffered from the infection which eventually vanished spontaneously from the Dominion. After an account of the life cycle of *W. bancrofti* and of its epidemiology the author states that any doubts as to the susceptibility of Europeans to the infection which is rare among those in the Pacific under peace-time conditions were dispelled in 1942 on the entry of U.S. marines into the Samoan area. 38,300 men were exposed to risk of infection in areas of high filarial endemicity and 10,421 of them were considered to have become infected.

The diagnosis in the early cases was delayed owing to the lack of familiarity of medical officers with the disease but once its occurrence was recognized all cases on diagnosis were removed at once to the United States. The high infection rate in the marines in the Samoan area was not paralleled elsewhere with an equally high native incidence of the condition. The author explains this as being due to the greater segregation of the troops from the natives in these latter areas and to the differences in the habits of the vectors which in Samoa bite by day. The manifestations of the early disease (as recorded recently by numerous American workers) were quite unlike the text book descriptions of the later stages seen in natives reinfected over a period of years. Lymphangitis, lymphoedema and lymphadenopathy are the cardinal early signs and appear after exercise, subsiding with rest in 3 to 5 days. Details are given of the anatomical location of these signs which were sometimes associated with mild malaise, a slight leucocytosis and low-grade fever. Only 18 (0.07 per cent) of 2,590 patients seen over a period of 17 months had to be admitted to hospital for a flare-up of the disease. Fears of sexual sterility, impotence and elephantiasis were soon relieved in the psychologically sound and were proved by subsequent history to be quite unfounded. Diagnosis of the early infection is by no means easy and has to be inferred on clinical grounds. Examination of the skin reaction to a filarial antigen gave approximately 85 per cent of positive results in the infected but 15 per cent of normal persons gave false positive reactions.

The signs of early filariasis—happily in the absence of any specific treatment—vanish spontaneously if the patient is removed from the possibility of further infection. There is little reason to anticipate the re-establishment of the disease in the United States as an aftermath of the war in view of the light and transient infections being introduced there by the servicemen and of the fact that when introduced on a more lavish scale in the past in the highly infested slave population it failed to maintain itself and died out spontaneously. Release to civil life of the infected veterans can therefore proceed without danger to the community or to the individual. A. R. D. Adams

DEFICIENCY DISEASES.

KING W D & SEBRELL, W H Alterations in the Cardiac Conduction Mechanism in Experimental Thiamine Deficiency *Pub Health Rep Wash.* 1946 Mar 22, v 61 No 12 410-14 3 figs (2 on 2 pls.) [33 refs.]

Various cardiac changes associated with thiamin deficiency have been reported. They include in man, shortening of the PQ conduction time, inversion of T waves increased QRS interval to bundle-branch block, sinus arrhythmia, sinus arrest premature beats auricular tachycardia, and tachycardia in rats bradycardia, shortened or lengthened PR interval, T wave and ST segment changes in pigeons heart block, tachycardia and inverted T waves in dogs deviations of the T wave, lengthening of the QT interval and tachycardia in swine bradycardia, prolonged PR interval, second-degree A V block abnormal P waves inverted T₁ nodal and ventricular premature beats, A V dissociation, complete heart block with ectopic ventricular rhythm, and auricular fibrillation. Many of these changes were associated with widespread necrosis in the myocardium.

Experiments with rats on a thiamin-deficient diet (except during periods of acute deficiency manifested by spasticity ataxia and convulsions at which time the animals were given 50 microgrammes of thiamin subcutaneously) showed that the average heart rate of the deficient animals decreased to 369 beats per minute progressively over a period of six weeks compared with a rate of 456 beats per minute for control animals and that in the deficient animals there was a progressive widening of the PR and QRS intervals as well as an increase in the amplitude of the QRS and T deviations. In 4 of 11 animals auricular fibrillation occurred during their first acute deficiency episode. In 3 of the 4 rats normal sinus rhythm was restored within 24 hours by the administration of thiamin, the fourth animal dying within 24 hours. In 4 of 11 animals during their second or third acute deficiency attacks, auriculo-ventricular nodal rhythm was observed one of the animals having previously shown auricular fibrillation. Premature beats, ectopic beats bigeminy auricular standstill and a shifting pacemaker were commonly found among the deficient animals. In two rats, auriculo-ventricular nodal rhythm was not converted to normal rhythm by large doses of thiamin and in one rat sectioning the vagi did not alter the auriculo-ventricular nodal rhythm.

The changes appear to be the result of abnormal tissue metabolism, and might be expected to vary in degree and persistence early or slight abnormalities being reversible and more severe deviations representing permanent damage to the tissues.

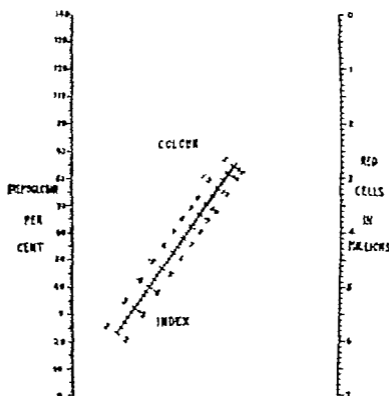

A clinical correlation between thiamin deficiency and thyrotoxicosis has been noted, and the similarity of the cardiac manifestations of thiamin deficiency and those of acute rheumatic fever in young adults has been commented upon. Consequently since auricular fibrillation may occur in experimental animals apparently as the result of chronic thiamin deficiency a possible factor in the cause of this arrhythmia in thyrotoxicosis rheumatic heart disease and the auricular fibrillation of unknown origin is suggested.

HAEMATOLOGY

FREEDMAN B J Colour Index Nomogram. *Brit Med J* 1946 June 1
838 1 diagram.

The colour index is read by placing a ruler on the appropriate points on the red cell and haemoglobin scales the point of intersection with the middle scale giving a direct reading

Colour index nomogram.

[Reproduced from the *British Medical Journal*]

To construct the nomogram draw two parallel vertical scales about 5 in. apart 1 in. on the scales representing 1 million erythrocytes and 20 per cent haemoglobin respectively the oblique scale is made by joining the two zeros and is calibrated by laying a ruler across the 5 million mark and the various haemoglobin percentages. It might be drawn on a card and varnished.

J F Corson

DARBY W J The Oral Manifestations of Iron Deficiency *J Amer Med Ass* 1946 Mar 30 v 130 No 13 830-35 3 figs. [Refs in footnotes.]

Six cases are described in which fissures at the angles of the mouth and superficial glossitis producing atrophy of the papillae accompanied chronic anaemia of iron deficiency type. Some of these cases were greatly improved or cured by iron therapy alone others responded to administration of iron after prolonged treatment with various preparations of the vitamin B complex.

The first of these patients a woman of 42 years had 10.5 gm. haemoglobin per 100 ml. She complained of rawness and burning of the tongue and lips

prunus vulvae listlessness and fatigue constipation and an attack of diarrhoea. Examination of the mouth showed fissures at the angles and a swollen dusky tongue with atrophy of the papillae. Treatment for 9 weeks with a mixture providing 12 mgm. thiamin 4 mgm. riboflavin and 100 mgm. nicotinic acid daily led to no improvement. She was then given 0.3 gm. ferrous sulphate thrice daily. Within a week there was marked subjective improvement. Within 3 weeks the tongue appeared normal the fissures were healed, and the prunus vulvae had gone. Iron therapy was discontinued after 5 months and the patient remained well during the succeeding 5 months.

The author believes that iron deficiency alone is a common cause of oral lesions that are confused with signs of deficiency of vitamin B. In his own clinic these signs are more commonly due to iron deficiency than to deficiency of nicotinic acid or riboflavin.

[It is unfortunate that the illustrations are so poorly reproduced as to be almost valueless.]

DERMATOLOGY AND FUNGUS DISEASES

ALLEN R. F. & GOODALE R. H. Pinta like Lesions among Natives of Guam. *U.S. Nav. Med. Bull.* 1946 May v. 46 No. 5 653-62 6 figs. [31 refs.]

In Guam particularly in the southern half of the island, a condition known as *peladang* is to be seen among the natives. It is characterized by hyperpigmentation of some and loss of pigment on other areas, on face, hands and feet. The authors found 39 such cases among 2,006 natives inspected. 12 were males, 27 were females and their ages ranged between the wide limits of 21 and 83 years. Lesions started as small hyperpigmented areas with itching for a few days. These areas spread, and later the pigment was lost. There was no pain nor any systemic disturbance. Depigmented areas were greyish-white as a rule. In two patients they were of a pink colour. Biopsy sections showed atrophy of the epidermis and flattening of the *rete* layer. The dermis was infiltrated with lymphoid cells and oedematous, with chromatophores concentrated in the upper layers. The *stratum corneum* was thickened. Twenty-two out of 29 patients tested gave a positive Kahn reaction, but only 56 were positive among 1,000 control natives. Dark field examinations were made of serum from six patients, but no spirochaetes were seen.

Because much of the study of pinta has been carried out in Mexico, South America and the Caribbean islands, the disease has been thought of as almost entirely American, but it occurs also in Algeria, the Philippines, Malaya, Egypt, India, Ceylon, the Gold Coast and the Marshall Islands.

BERLIN C. Degeneratio Colloidalis Solaris. *Harefuah* Jerusalem. 1946 May 15 v. 30 No. 10 [In Hebrew 240-41 2 figs. English summary 241.]

The colloid degeneration of the skin is a common disease in sunny countries. It affects fair-skinned individuals in advanced middle age with outdoor occupations. The eruption is strictly limited to the uncovered surfaces,

particularly the upper half of the face and the back of the hands. The morphological picture is variable. The familiar picture [is that] of small yellow closely aggravated [aggregated?] papules or pseudo-vesicles [but] one may find also smooth unelevated, shiny diffuse or island-like spots as well as rough and uneven structures closely resembling citrus peel.

The colloid degenerated skin is vulnerable brittle and tends to bleed. This condition was previously described by the author as *Purpura Solaris*. The nail phenomenon the appearance of a purpura streak after moderate to heavy pressure with the free border of the nail is pathognomonic of colloid degenerated skin and is of great diagnostic value in atypical forms.

Owing to the important role played by the sun in the production of this clinical entity the name degenerative colloidalis solaris is suggested for it by the author.

HEAT STROKE AND ALLIED CONDITIONS

RENBOURN E T. Observations on Normal Body Temperatures in North India. With a Statistical Analysis by F F BONSALL. *Brit Med J* 1946 June 15 909-14 9 figs

The body temperatures of 894 soldiers—British and Indian—were recorded during the period from March to September 1945 at Dehra Dun North India. clinical thermometers were used and both oral and rectal temperatures were taken but not in every individual. Altogether 1,800 temperature recordings were made. The British soldiers had been in India for periods ranging from 4 months to 2 years. The figures of various records of groups of men are shown in tables and diagrams and are examined statistically and the original paper should be consulted for the details.

The following are some of the results and conclusions: oral temperatures up to 100.6°F and rectal temperatures up to 101°F may occur in normal individuals. the temperatures of British and Indian soldiers were much the same and acclimatization does not seem to be an important factor. resting oral temperature showed no correlation with erythrocyte sedimentation rate nor with the presence of prickly heat. temperatures rose slightly with the onset of the hot weather and fell at the end of the monsoon period. temperatures varied during 24 hours by from 1 to 2.6°F in 90 per cent of 36 diurnal curves of 14 individuals. exercise in the rain may cause a fall in oral temperature but in dry weather it causes a rise.

REES W H & OGDEN L W. Some Observations upon the Effect of Colour on the Absorption and Emission of Radiation by a Textile Fabric. *J Textile Inst* 1946 Apr 37 No 4 T113-20 3 figs

This very concise paper deals with experimental tests which have yielded much needed information in regard to the relative effects of colour on the absorption reflection and emission of radiation falling within specified ranges of wavelength.

Samples of a standard poplin fabric dyed in a wide variety of colours were exposed to radiation from a high-intensity carbon arc emitting wavelengths closely corresponding to those in natural sunlight over a range of 0.2 to 1.5

[September 1946]

microns and to medium temperature radiation from an electric radiator at 900°C emitting visible red and infra-red wavelengths with a maximum emission of about 2.5 microns.

Experiments are also described which provided data for the emission of radiant energy by coloured samples of the fabric kept at approximately a body-surface temperature of 36°C viz for wavelengths ranging from 5 to 16 microns.

It is pointed out that as far as radiation is concerned clothing may be required for two distinct purposes to protect by reflection or non-absorption of solar radiation as in the tropics and to reduce body heat loss due to radiation as in cold climates.

In the experimental method employed for determining the effects of colour on the rate of absorption of radiant energy two kata thermometers one of which was clothed with a tight fitting sleeve of the fabric sample under test, were simultaneously exposed to radiation from the high-intensity carbon arc or from the electric radiator.

In the experiments on emissivity a Moll microthermopile and sensitive galvanometer were used to observe the emission of low-temperature radiation from a black body at 36°C and from various samples of coloured fabric held in close contact with the sides of a copper cylinder kept at 36°C. The true emissivity of the fabric was calculated from the observed emissivity by applying a correction to allow for the slightly lower temperature of the external radiating surface of the fabric.

The results of the tests are given in a table from which the following data have been abstracted

COLOUR

Dyed cotton fabric	RELATIVE ABSORPTION (taking Sulphur Black as unity)		EMISSIVITY (% of perfectly black body) For surface temperature at 36°C
	For radiation from high intensity arc	For radiation from electric radiator at 900°C	
Sulphur Black	1.00	1.00	100
Vat Black	0.80	—	98
Vat Yellow	0.51	0.99	98
Vat Orange	0.52	0.99	98
Azoic Red	0.54	0.99	98
Vat Blue	0.61	0.99	98
Vat Green mixture	0.61	0.99	98
Vat Violet	0.61	0.99	98
Direct Khaki	0.59	—	98
Sulphur Khaki	0.50	0.98	98
Bleached (White)	0.69	—	98
Aluminium foil	0.89	—	98
	0.04	1.00	98
		<0.10	98

It is observed that while the colour of a fabric is a most important factor in determining the absorption of solar radiation it is of no importance in determining the emission at the long wave lengths associated with body temperature, and even with radiation from the electric radiator at 900°C, the differences between the colours are very small. At body temperature a textile (non metallic) fabric whatever its colour behaves practically like a black body.

in respect of the emission or absorption of long-wave radiation associated with such a temperature namely having the capacity for maximum emission maximum absorption and minimum reflection

It is noted that the properties of very low emissivity and low absorption possessed by aluminium foil are made use of in military topees and the design of tropical tents for the purpose is referred to the fact that colours which appear roughly alike to the eye may have markedly different absorption characteristics particularly for the near infra red wavelengths which account for approximately 20 per cent of the total energy in sunlight at earth level

The concluding part of the paper draws attention to the fact that the characteristics particularly for the near infra red wavelengths which account for approximately 20 per cent of the total energy in sunlight at earth level radiation does give a minimum absorption in the near infra-red region should be selected. A plate showing infra-red photographs of the dyed cotton fabric is included in the paper and the problem of camouflage is referred to

MISCELLANEOUS DISEASES

SMITHBURN K. C Semliki Forest Virus. III. Propagation of the Virus in Developing Chick Embryos. *J Immunology* 1946 Apr v 52 No 4 309-14 1 fig

This paper records the successful propagation of the Semliki virus through 33 serial passages in the embryo chick (for a description of this virus see this *Bulletin* 1945 v 42 320) The series of passages was initiated with a filtrate prepared from an infected mouse brain injected into the region of the developing chick embryo [see ELMENDORF and SMITH this *Bulletin* 1937 v 34 692] Eggs incubated for 7-9 days prior to inoculation were employed and passage was performed with a filtrate of ground-up embryo Virus multiplied readily and embryos succumbed between the 11th and 24th hours after inoculation Tests for the presence of virus were made by intracerebral inoculation in mice. The infective titre of embryonic chick tissue varied between 1 in 3.65×10^8 and 1 in 210×10^8 and there was no decline on passage. Detailed experiments showed that virus could be detected in the developing embryo from about the 4th hour of incubation onwards The virus content seemed to remain more or less stationary after the death of the embryo The curve of multiplication proceeded up to 12 hours by logarithmic progression. Beyond that point there was a flattening of the curve but a further absolute increase. Macroscopically the embryos showed varying degrees of hyperaemia and haemorrhage. Microscopic examination showed dilatation and congestion of vessels and extravasations especially in the subcutis Necrosis of cells occurred only to a slight extent and was not marked in any special tissue.

A J Rhodes

WINKENWERDER W L Asthma—as observed Overseas in a General Hospital in the Southwest Pacific Area—with special reference to Relationship of Tropical Service to Onset and Recurrence. *Bull. Johns Hopkins Hosp* 1946 Feb v 78 No 2, 78-95

It is a curious fact that none of the standard works on tropical medicine deals with or even comments on, the ill effects of tropical climate and conditions on the asthmatic state or on the tendency for asthma to develop in such circumstances This article has therefore a special value since it attempts to treat the subject scientifically

The facts presented are based on a study and analysis of 209 cases among 352 American soldiers admitted to a South Western Pacific General Hospital during a period of two years ending July 1944 on account of asthma. These were readily divisible into two groups of nearly equal numbers—107 who had suffered from asthma prior to enlistment, and 102 who developed it after entering the service.

Among those in Group I a personal history of hay fever or asthma was elicited in 74 (69.1 per cent) and a family history in 59 (55.1 per cent) as compared with 48 (47 per cent.) and 30 (29 per cent) in Group II. The time elapsing between arrival in the tropics and recurrence or aggravation of the older-standing asthma was noted in 74 patients—in 62 (83.7 per cent) it was within 3 months and in 46 (62 per cent) within one month, whereas among 61 who had no previous history of previous attacks 46 (75 per cent) developed symptoms in 3 months, 3 within a week, 14 within a fortnight and 27 within a month. The monthly distribution was examined in 104 of Group I and 61 of Group II. April and May accounted for 33 (31 per cent) of the former and most cases, 16 of the latter occurred in May, but the author on further study came to the conclusion that the date of arrival rather than environmental factors controls the monthly distribution of recurrence onset.

Several pollen extracts and inhalant dusts were tested for allergy of patients. Of 48 of Group I tested against the former 35 were positive, as compared with 22 of 25 in Group II. 74 out of 86 of Group I tested with inhalant dusts were positive and 46 out of 76 of Group II.

Attempts were made also to evaluate the immediate precipitating cause or combination of causes. Among those of Group I 2 were thought to be directly due to pollen alone, 49 to pollen and inhalants, 37 to inhalants alone, 5 to upper respiratory infection (sinus trouble, polyp, chronic tonsillitis) and 4 to lower respiratory infection, such as bronchitis or pneumonia. The respective figures in Group II were 0, 15, 12 and 20 to respiratory infections (no distinction is made between upper and lower) in 54 instances no determination could be reached.

Duration of disability differed in the two groups. In the first, the minimum and maximum days stay in hospital were 5 and 224 with an average of 80.24. In the second the respective figures were 6, 181 and 57.7 days. Desensitization was undertaken in a few cases—28 to inhalant dusts, 3 to pollen and inhalants combined and 7 to histamine. No valid conclusion as to the efficacy of these procedures was reached but in a small number of cases, such treatment appeared to be beneficial and aided the patient to remain on duty. [As stated, this is an important article although the number of patients was small. Abstraction has been difficult because many of the figures and calculations based on them are erroneously stated.]

H. Harold Scott.

MEARON I. G. K. Tropical Eosinophilia: some further Observations. *Indian Med. Gaz.* 1946 Feb v 81 No 2, 70-73 [10 refs.]

An interesting series of observations showing that the so-called tropical eosinophilia though most of the cases have been reported from India and Ceylon has in reality a wider distribution being found in China, Havana, America, Tanganyika, Samoa and other places. The author gives details of blood counts in patients with asthma, and useful diagnostic deductions therefrom. Thus, in one case with a total leucocyte count of 9,800 per cmm. & 12 per cent. eosinophilia and an erythrocyte sedimentation rate of 2 and 5 mm. in one and two hours a diagnosis of asthma may be made with practical certainty. In another with a total of 10,000 an eosinophilia of 43 per cent and sedimentation rates of 10 and 30 W.R. negative and no response to

arsenic the diagnosis is in favour of asthma as against tropical eosinophilia. In a third with 13 000 leucocytes per cmm. 25 per cent eosinophiles without lung signs there was a personal and family history of asthma. But the patient was a child whose blood gave strongly positive Wassermann and Kahn reactions while in the parents they were negative and rapid improvement followed the giving of stovarsol. Hence the diagnosis is in doubt and the weight of evidence seems to be more on the side of tropical eosinophilia. Lastly an adolescent with a history of asthma with fever and cough a total white cell count of 49,500 an eosinophilia of 79 per cent sedimentation rates of 39 and 88 in one and two hours respectively strong Wassermann and Kahn reactions and response to arsenic. Here the diagnosis would be tropical eosinophilia in a previously asthmatic subject. Intrapentoneal inoculation of blood of a tropical eosinophilia patient into guinea-pigs yielded inconclusive results but only a single injection was given. The effects point equally well to infection or to reaction to a metabolic product derived from the organism or the patient's tissues. Further work is necessary in this but up to the time of writing the author had not been able to obtain fresh blood from a typical case of the disease.

H Harold Scott

JUNTER E. A. A Case of Tropical Eosinophilia (Weingarten's Syndrome) [Memoranda.] *Brit Med J* 1946 June 8 877

The patient was a European man aged 37 who had spent 12 years in Nigeria and during that period had suffered only from infective jaundice and subtertian malaria. Within 6 months of his return to England he began to have attacks of asthma at night with paroxysmal cough and orthopnoea the attacks were not very severe or prolonged. A skiagram of the chest was normal. A blood count made during an attack of malaria, showed 12 400 leucocytes with polymorphonuclears 20 per cent and eosinophils 59 per cent and there were some myelocytes. There were no signs of helminthic infection. No treatment was given and during the following year he had occasional attacks of asthma and another attack of malaria. About 18 months after the first attack of asthma he had a febrile attack lasting for some days with nocturnal asthma and widespread urticaria. His blood showed 36,200 leucocytes with polymorphonuclears 10 per cent and eosinophils 70 per cent. He was given three injections of neoarsphenamine (N.A.B.) at weekly intervals and improved rapidly when last examined his blood showed 5 800 leucocytes with polymorphonuclears 58 per cent. and eosinophils 5 per cent.

J F Corson

VAN DER SAR A. Pulmonary Acanthosis. Its Relationship to the Eosinophil Lung and Löfller's Syndrome. *Amer Rev Tuberculosis* 1946 May 53 No 5 440-46 8 figs [14 refs]

Writing from Curaçao the author gives a record of eight patients ranging in age from 8 to 48 years four of whom were sufferers from asthmatic attacks for short periods two of them for 3-5 weeks two for 3-4 months worse at night. The other four suffered from bronchitis but not asthma one had tuberculosis of the lungs. It is interesting that two of the patients were sisters living in a house where within the preceding 3 years two patients had suffered from tropical eosinophilia. In the sputum of each of the eight mites were found in one an adult *Tyroglyphus* in the others hypopal stages. They are well shown in photographs. X rays revealed enlarged hilar markings fine mottling and pulmonary infiltrations except in one case in which nothing abnormal was found. Blood examination showed leucocytosis ranging between 12 000 and 20 700 per cmm. with eosinophiles up to 80 per cent. at the beginning of

observations and final percentages between 4 and 11 after treatment four with malarial injections [no dose stated] every 5 days, the others with carbazon [presumably carbazone] 3 times a day for 10 days [again no dose mentioned]. The total counts (after treatment) were normal (6,800 to 9,100) in seven reduced in one (4,500) the eosinophile percentage in two patients was reduced to 4 in two others to 5 and 7 respectively to 8 in three the one with 11 per cent had the lowest early total count 12,000 per cmm. [Many other observers have not found mites in the lungs and sputa of patients with tropical eosinophilia and the author seems to be begging the question in his conclusion. The question why in some cases the mite infection manifests itself as tropical eosinophilia in other cases as Löffler's syndrome and without any roentgenological abnormalities while a leucocytosis with eosinophilia persisted, must remain unanswered for the time being. It is still a moot point whether tropical eosinophilia and Löffler's syndrome are really different diseases.]

GENERAL PROTOZOOLOGY

ADAMS F. H. HORNS R. & EKLUND C. Toxoplasmosis in Large Minnesota Family. *J Pediatrics* 1946 Feb. v 28 165 [Summary taken from *J Amer Med Ass* 1946 May 18 v 131 No 3 259]

Adams and his co-workers studied a typical case of toxoplasmosis in a 14-year-old girl who was a member of a large Minnesota family. The patient had 10 living siblings and 5 other close relatives. Complete physical studies including funduscopic examinations, were made on 11 members of the family. Neutralization tests against the toxoplasma organism were done on blood serum from these and four other members of the family group. Positive neutralization tests against the toxoplasma organism were present in the patient, her mother and 8 of 9 siblings tested. The mother and the 9 siblings had no clinical symptoms or signs of toxoplasmosis as determined by physical and roentgenologic examination. Whether infection in this patient and her siblings was congenital or acquired could not be ascertained.

KARNAKY K. J. Trichomoniasis. A Twelve Year Study. *Western J Surgery Obstet & Gynecol* 1946 Feb v 54 No 2 61-4 2 figs.

The author who has been studying *Trichomonas vaginalis* infections for some 12 years gives in this paper his experience as regards diagnosis and treatment. For the former discovery of the organism by microscopic examination is essential though the occurrence of a secretion which "scalds" the external genitalia is very suggestive. For treatment the best results have been obtained by inserting Fluorquin tablets twice daily for 12 days, followed by douching with a vinegar lotion two or more times a day for at least three months.

GENERAL ENTOMOLOGY

HADDOW A. J. The Mosquitoes of Bwamba County, Uganda. IV. Studies on the Genus *Eretmapodites* Theobald. *Bull Entom Res* 1946 May v 37 Pt 1 57-82 9 figs [10 refs]

In 1941 after the isolation of the yellow fever virus from a human patient and from wild-caught mosquitoes in Bwamba intensive entomological investigations were started and are still proceeding. The topography and vegetation of the area has already been described and the results of day and night mosquito catches have been discussed [see this *Bulletin* 1946 v 43 79 80 255]

The present paper is chiefly of interest to the medical entomologist as it concerns the taxonomy and bionomics of eight species of mosquitoes of the genus *Eretmapodites* which occur in Bwamba. One of these is new to science (*E. ferox*) and is described. The larva and pupa of *E. snornatus* and the larva pupa and female of *E. penicillatus* are described for the first time. The author criticizes the diagnostic value of certain characters used in existing descriptions and keys and gives amended keys to the known males females pupae and larvae though some species still have to be grouped together.

Eggs of *Eretmapodites* are laid in small numbers at frequent intervals at the edge of small collections of water in such things as fallen leaves plant axils and snail shells. The eggs sink and are unable to withstand desiccation. Many experiments show that larvae of the Bwamba species prey on other small aquatic animals including mosquito larvae. Pupae move sluggishly and sometimes lie on one side as if dead. The genus is confined to forest and dense vegetation and females bite by day particularly in the late afternoon 6,500 In 1928 Bauer successfully transmitted yellow fever to rhesus monkeys by the bite of *E. chrysogaster* a species which will breed in small cages. The yellow fever virus has not yet been isolated from specimens taken in Bwamba though three strains of a virus related to that of Rift Valley fever have been isolated. It is suggested that species of *Eretmapodites* may include transmitters of human and animal viruses.

DA CRUZ FERREIRA F & DE MEIRA M. T. V. Espécies de *Phlebotomus* de Lisboa e arredores. II. Sobre a presença de *P. ariasi* Qem Lisboa. [*Species of Phlebotomus found in Lisbon and its Environs. II. On the Female P. ariasi* in Lisbon.] *An Inst Med Trop Lisbon*. 1945 Dec v 2 207-15 2 figs (1 on pl) [14 refs] English summary

The authors have studied the morphology and recorded measurements of six specimens of female *P. ariasi*. In a detailed table they give their own findings and for purposes of comparison those of RAYNAL and LE GAC (1933) PARROT (1936-40) and ZARIQUEY (1937). They give the measurements of the head thorax abdomen palps antennae the wings the three pairs of legs and the spermathecae.

In a separate section of this article they record their study of over 4,000 specimens of *Phlebotomus* captured in Portugal during 1944. By far the majority were *P. perniciosus* 96.7 per cent. *P. minutus* came next 2.7 per cent. *P. ariasi* 0.4 and *P. sergenti* 0.2 per cent. The last were most common in fowl runs the others in human dwellings. The relative proportions of the sexes were *P. perniciosus* twice as many females as males *P. minutus* in equal proportions *P. ariasi* three males to one female *P. sergenti* five males to one female.

COOLEY R. A. [Senior Entomologist] & KOHLs Glen M. [Assoc. Entomologist U.S. Pub. Health Service] *The Genus Ixodes in North America. Nat. Inst. of Health Bull. No 184* Wash. 1945 iii+248 87 figs. [40 cents.]

This monograph contains an account of the principal characters of the genus *Ixodes* with separate keys to females males and nymphs. These preliminaries are succeeded by systematic descriptions of 41 species females males and nymphs are considered separately for each species the various points being illustrated in line drawings, and there is a section for each species on hosts and geographical distribution in the United States, with a map. At the end there is a note on doubtful species a table showing geographical distribution, a classified list of hosts, and a list of references.

The monograph is of the high standard usually maintained in this series of National Institution of Health Bulletins and will be an invaluable work of reference to those interested in the subject

WISNUP C. B. BROTHERS W. C. & EIDE, P. M. Airplane Spraying of Rice Fields with DDT to kill Mosquito Larvae. *J. Econom. Entom.* 1945 Dec., v 38, No 6 686-8.

Rice fields in Stuttgart Arkansas are first flooded when the rice is young in June then allowed to dry for the control of insect pests and then again flooded, in intention continuously throughout July and August. In practice however there may often be a series of alternate floodings and dryings during these months, and ideal breeding conditions for mosquitoes of the genus *Psorophora* and for *Anopheles quadrimaculatus* are produced. DDT applied from aircraft in xylene water emulsion at the rate of 0.1 lb. or more per acre gave perfect initial control of breeding up to mid-July when the thickening vegetation made bigger doses necessary of the order of 0.5 lb. per acre.

Under circumstances of this type it is essential that large areas of crop should be treated simultaneously, and therefore most desirable that some larvicidal effect be produced in fields which, though dry at the time of spraying, are flooded soon after. Very efficient pre-flooding control of this type was secured against *Psorophora* with doses of 0.2 lb. per acre or over. Against *A. quadrimaculatus* doses of 0.1 and 0.2 lb. per acre gave doubtful or no pre-flooding control, and of the two trials with 0.5 lb. per acre one gave good and one doubtful control.

Doses under 0.5 lb. per acre had a residual effect for about two weeks, during which no larvae were seen though mature larvae were not seen for a considerably longer period. With doses of 0.5 lb. per acre the initial complete elimination was maintained for three to four weeks.

No damage to developing rice could be observed during the season and random counts of heads of rice from treated and control blocks showed no difference in the number of plump grains that had been produced.

FENNAN R. G. Preliminary Tests with DDT against Insect Pests of Food-Crops in the Lesser Antilles. *Trop Agriculture* Trinidad. 1945 Dec., v 22, No 12 222-6

This paper which is mainly concerned with the agricultural uses of DDT includes a table showing the mortality amongst about 40 species of insects of agricultural importance after exposure to standard doses of DDT. The author considers that in view of its concomitant effect on beneficial insects the question of whether DDT should be used on any particular crop in any particular Colony can only be settled by considering each case separately in the light of existing local circumstances. In the case of the major food-crop pests in the Windward and Leeward Islands there is little objection to its use.

A spray of DDT emulsion at 200 mgm. per sq. ft. on and around manure heaps had an immediate effect in controlling flies but little residual effect owing to the normal disruption of the surface which exposed untreated portions to which flies could gain access without damage. As a method of fly control in dairies it was concluded that complete treatment of exposed manure heaps at frequent intervals should be combined with limited treatment of carefully selected surfaces in the dairy such as hanging fixtures, sides of windows and doors, sunlit areas on walls and floor in the food mixing room, the mixing trough and the surfaces of sacks of feed. *G Macdonald*

STANMERS F. M. G. & WHITFIELD F. G. S. Toxicity of DDT to Man. [Correspondence] *Nature* 1946 May 18 658 [Summary appears also in *Bulletin of Hygiene*]

At the Royal Naval School of Tropical Hygiene in Colombo a team of 15 men (1 Tamil and 14 Sinhalese) was employed continuously for 5 to 7 months in preparing and spraying a kerosene solution of DDT (5 per cent). On an average 24 hours per week were actually spent in spraying. At the beginning protective clothing and gauze masks were issued but owing to the heat the men refused to wear these protective devices. Most of the spraying was done in confined spaces and the men were often exposed to splashes and drip from the ceilings as well as to leakages from the sprayers (which received rather hard treatment). After a day's operations a white frost of DDT crystals could be seen on exposed portions of skin while overalls were frequently saturated.

Despite this very considerable degree of exposure to DDT none of the men developed signs or symptoms of intoxication. Each man was questioned as to general fitness and received a clinical examination. Liver function was estimated by the oral hippuric acid synthesis test, and haemoglobin estimations, red and white-cell counts including differential white-cell counts were made. Examination of urine for abnormal constituents and stools for parasitic ova, worms and cysts were also carried out. Similar examinations were made on a control group of men. No evidence of ill-health due to DDT was detected.

MONROE A. F. The Serum Albumin and Globulin Levels in Africans as compared with Europeans with a Note on Technique. *Ann Trop Med & Parasit* 1948 Apr v 40 No 1 29-33 2 figs.

The serum albumin and globulin levels in 30 healthy young Africans serving in the army in the Gold Coast were compared with those of 30 Europeans from the Army in the area, all of whom had been in the tropics for some time. Proteins were fractionated by the cold methanol technique of PILLEMER and HUTCHINSON (*J Biol Chem* 1945 v 158 299). The results by this method agree with those found by electrophoresis: the albumin/globulin ratio is about two-thirds of that given by neutral salt fractionation. A technique is described for filtering off the precipitated globulin without allowing the temperature to rise above 2°C. in spite of tropical conditions, and without special apparatus.

The results are summarized in the following table —

Mean levels	Albumin gm per cent	Globulin gm per cent	Total Protein gm per cent	Albumin/ Globulin gm. per cent.
Africans	3.45	3.76	7.21	0.83
Europeans	4.3	2.58	6.88	1.7
Significance of differences	—	+	Doubtful	+

Even lower albumin globulin ratios were found in other cases: e.g. in five pregnant women, 0.43-0.7; in five children with nutritional deficiency, 0.3-0.9; in one case of hepatic cirrhosis, 0.1

ADAMS Margaret A. & BALLOU Alice N. A Comparison between the Values for Plasma or Serum Protein as obtained by the Specific Gravity and the Micro-Kjeldahl Methods. *J Lab & Clin Med* 1948 May v 31 No 5 507-13 2 figs. [12 refs.]

1. One hundred and twenty-eight cases are presented in which the serum protein concentration was determined by both the micro-Kjeldahl procedure and by the copper sulfate specific gravity method.

2. In fifty-five of the 128 cases, or 44 per cent, the differences between the total protein values by the two methods did not exceed 0.3 Gm. per 100 c.c. of serum. The percentage of cases showing such agreement was slightly lower when the albumin was below normal or the globulin above normal. When 0.2 Gm. per 100 c.c. is taken as the criterion for duplication, only 35 per cent of the cases showed such agreement.

3. No conclusions could be drawn as to the type of patient in whom the serum specific gravity is influenced by factors other than the protein content.

4. The correlation between the specific gravity of serum and its protein content was found to be too low to permit the use of specific gravity determinations for reliable estimation of serum total protein."

REPORTS SURVEYS AND MISCELLANEOUS PAPERS

KEAN B. H. Causes of Death of Children on the Isthmus of Panama. *Amer J Dis Children* 1946 Apr v 71 No 4 351-6

Complete post mortem examinations were made on 2,132 children under 11 years of age who died in the Isthmus of Panama during the 39 years from 21 October 1904 to 7 November 1943 histological sections were examined in nearly all cases. The children included British West Indian Negroes Panamanian mestizos (mixed Indian Spanish and Negro) and United States Whites. The causes of death the primary cause being selected are given in a table in which total cases groups in three periods of the 39 years sex groups and groups of race or origin are shown. Half of these deaths were due to —

Tuberculosis 217 malaria, 92 bronchopneumonia, 160 lobar pneumonia, 59 diarrhoea and enteritis 180 bacillary dysentery 29 congenital debility (under 1 year) 271 premature birth 184

The author does not discuss the subject.

LOWE J Some Recent Advances in Tropical Medicine. *Indian Med Ga.* 1946 Feb v 81 No 2, 86-96

CONNECTICUT STATE DEPARTMENT OF HEALTH Nomenclature of Pathogenic and Parasitic Organisms [OSBORN S H M.D. C.P.H. Commissioner Hartford, Connecticut 66 pp 1945 [Summary appears also in *Bulletin of Hygiene*]

This booklet is intended as a companion and supplement to the Physicians Guidebook to Public Health Laboratories published by Connecticut State Department of Health [*Bulletin of Hygiene* 1946 v 21 151]. It contains lists of the scientific names of organisms arranged in eight sections and in alphabetical order of genera in each section with short notes on each species. The sections include bacteria, rickettsiae fungi, protozoa and worms. The nomenclature of the bacteria is with few exceptions that of Bergey's *Manual of Determinative Bacteriology* 5th Ed. although that manual was being revised the author decided not to delay the publication of this booklet until the appearance of the revised edition. In the case of the fungi, Dodge's *Medical Mycology* was taken as the authority in other sections authorities were more in agreement as to the nomenclature. There is an alphabetical index at the end of the book.

This booklet will be very useful to medical practitioners in connexion with laboratory reports and in other ways.

BOOK REVIEWS.

NAPIER, L. Everard [Companion of the Order of the Indian Empire F.R.C.P., etc.] *The Principles and Practice of Tropical Medicine*. pp xvi+917 195 figs. & 24 pls (4 coloured) 1946 New York The Macmillan Company 60 Fifth Avenue. [\$11 00]

On any count this is a good book. It is full, accurate readable and orderly and it gives throughout the impression that its author writes from an exceptionally wide personal experience, and that he has an enquiring mind. Where a point is in doubt he gives the arguments on both sides but generally makes up his own mind, one way or the other and says so. His writing is none the worse for a substratum of scepticism and a style which is at times sufficiently emphatic.

Napper makes it clear that he has written for the student, the practitioner and the public health worker and that the work is rather a textbook than a book of reference—but this is too modest a claim. He has deliberately omitted smallpox, typhoid fever, tuberculosis and the systematic mycoses but has included tularaemia. The chapters on bejel and leprosy were written by Dr H. SENKJIE and Dr John LOWE respectively and acknowledgment is made of the collaboration of Dr R. N. CHAUDHURI, Dr Sundara RAO and others. It is evident that the author has been at pains to secure expert advice on many subjects. In a footnote it is stated that the first part of the book was published in India in 1943 and that the completed work has now been published in the United States—it is now available in Britain. It has been possible to make a few additions to the first part but for various reasons these have had to be strictly limited. This probably explains why the outstanding work on mepracrine both for treatment and suppression of malaria, carried out in the later stages of the war is alluded to somewhat briefly and that the doses recommended in the body of the chapter on malaria, which derive mainly from an experience of partly immune persons, are not so high as those quoted later and found necessary for non-immune soldiers operating in malarious countries. Many short addenda, referring to recent work, are included in these earlier chapters, and in later editions will, no doubt, be fitted more closely into the text.

The first chapters deal with environment, and with climate and its effects, including heat stroke and allied conditions—these are full of good sense. Medical men will generally agree with the author in what he writes of exercise, diet, drinking, etc. but it is not easy to get these ideas into the minds of the non-medical white settlers in the tropics.

The chapter on malaria occupies about 70 pages. It is very full, and the clinical aspect is particularly well covered—perhaps rightly the vast subject of anti-larval measures of control receives only general treatment, readers being referred to the special literature on the subject. The spray killing of adult mosquitoes is described more fully but DDT needs more mention. Incidentally DDT is not a mosquito repellent as is suggested on p. 118. Writing of malaria control Napper remarks that 'The economic aspect will always be paramount in this imperfect world. One's first thoughts must be how much will it cost and will it pay?' The reviewer must dissent—it is his belief that a doctor's first business is to promote good health, that commercial considerations must give way to considerations of human welfare and that it is the duty of medical men to insist on this.

The chapter on kala azar is very good indeed. The author has had a vast experience of the disease (he has seen more than 10 000 cases), has done much original work and has been closely associated with the research conducted in India during the last quarter of a century. The result is a highly informative and authoritative chapter fully up to date. This however is not quite true of the chapter on trypanosomiasis. For instance a sentence on p. 201 suggests that man is less susceptible to infection with *Trypanosoma rhodesiense* than with *T. gambiense*; the remark that sleeping sickness may be transmitted during coitus might be deleted; no mention is made of transmission by *Glossina pallidipes*; control measures are not very fully discussed. Nevertheless the bulk of the chapter is good and accurate. The theory of drug resistance which appeals to the author—that it is a matter of selection of resistant strains of trypanosomes—also appeals to the reviewer.

The relapsing fevers, leptospirosis, the fevers of the typhus group, bartonellosis, yellow fever, dengue, plague, tularaemia, the undulant fevers, and melioidosis are all adequately described, and the account of cholera is on the same high level as that of kala azar—here again there is evidence of a very wide

personal experience of the disease. For infections with *Entamoeba histolytica* the author prefers to discuss amoebic dysentery as the primary manifestation and to treat the other lesions due to the same organism as complications or sequelae. amoebic hepatitis is given a separate chapter. The flat statements on pages 428 and 429 that chlorination of water does not kill cysts of *E. histolytica* need modification in view of the work of CHANG FAIR and their collaborators [this *Bulletin* 1942 v 39 313 1945 v 42 286 734] who have shown that the concentration of gaseous chlorine needed to destroy the cysts lies well within the range of practicable superchlorination. Sprue is well described and a separate section is devoted to hill diarrhoea which the author thinks is usually caused by mild infection with *Shigella flexneri* but occasionally by some climatic factor *per se*. Leprosy is described in an excellent chapter by Dr John Lowe whose long association with the disease is well known to readers of this *Bulletin*. It is enough to say that the account is full and clear and is in line with modern views. Yaws, pinta and bejel are considered together, the account of the last having been written by Dr Harry Senekjic. the treponemal aetiology of pinta is accepted.

The chapter on tropical skin ulcerations is followed by sections on lympho-granuloma inguinale and granuloma venereum and by a chapter on some common skin diseases.

Helminthic infections occupy 180 pages as befits their importance. The section on filariasis due to *W. bancrofti* contains much the same information as the separate paper which was reviewed in this *Bulletin* 1944 v 41 1054. The worms are classified in several ways (and there are three tables which the student will find most useful) but the final classification adopted for purposes of description is according to the main sites of the pathological processes they engender—intestinal parasites, parasites of lymphatics, subcutaneous tissues and serous cavities, blood flukes, liver and lung flukes, and worms that produce the main pathogenesis in their larval stage. It seems that any classification has unsatisfactory features. The accounts are excellent especially of those infections which occur in India. The nutritional disorders of the tropics receive full treatment and there is an interesting note on infantile cirrhosis of the liver by Dr R. N. Chaudhuri. The anaemias are briefly described and there are short chapters on snakes and rabies.

The author's experience has been gained chiefly in India, where he led an active and enquiring life for many years in contact with all that was best of medical research between the two wars. The emphasis of the book is therefore inevitably on Indian conditions and reflects the very great amount of research that has in fact been done there. It is primarily a clinician's book but the pathological and parasitological aspects are also very strongly written. It is not so full in matters of public health control but that is not peculiar to this text book. There is a great need for a modern book on tropical public health measures. As was stated at the beginning of this review, this is an excellent book which can be recommended without reservation. The author has a very individual style which is an added attraction, and there is no woolly writing.

Some of the half tone plates are not clear and the coloured plates could be greatly improved.

Charles Wilcocks

KRAUS Heriberto *Tratamientos Modernos de las Enfermedades Tropicales de Colombia. Guia para el Medico Practico* [Modern Treatment of Tropical Diseases in Colombia. A Guide for the Practising Physician.] 343 pp. 1945. Bogota.

This is a graduation thesis and in his foreword Professor Camargo says: Among us where scientific publications are so scarce the work of Heriberto

Kraus is meritorious. The title describes accurately the substance and aim of the work, which bears testimony to the zeal and application of the author and to his facility for abstracting and extracting but it contains no original contributions. It deals with most of the diseases met with in Colombia the causes transmission symptoms diagnosis and prognosis receive little more than a mere mention and the title does not warrant our expecting more but treatment is fully dealt with. Quotations and references abound in fact, the whole is a compilation, the authors quoted and the references to the literature being fully noted in each case. The author has made full use of the *Tropical Diseases Bulletin* of 228 foreign that is non-Colombian references no less than 155 are to this *Bulletin* and this is amply acknowledged in the author's introduction.

In the cases of malaria leprosy and yellow fever fuller descriptions of the clinical aspect are given in others the diagnosis section comprises merely a list. One example may be given. Under lymphogranuloma inguinale called here *Lymphogranuloma venereum* we are told that Brumpt proposes that the causal agent should be named *Mityagenella lymphogranulomatosis* nov. sp. and that in diagnosis the disease must be differentiated from soft chancre suppuration of the legs (presumably adenitis secondary thereto) tuberculous inguinal adenitis filarial adenitis inguinal herma gonorrhoea syphilis inguinal granuloma carcinoma or tuberculosis of the rectum, amoebic or chronic bacillary dysentery. No details are given regarding the general or differential diagnosis between these.

A work such as this does not call for a minute review. Suffice it to say that the work of extraction has been carefully done and consequently the Guide is a good one for the medical practitioner in the tropics at the present time. If it is to retain its usefulness revision will have to be frequent as new drugs are brought forward or new methods found beneficial and old ones replaced. There is no mention of food poisoning of any kind—rather a notable omission—and fish poisoning is concerned only with those which poison by their spines.

We have tested most of the directions and many of the references and found that the former are up to date and the references correct. Professor Camargo calls the work a minute and happy compilation of treatment which indeed aptly describes the publication.

H Harold Scott

PINEY A. [M.D. M.R.C.P. Physician, St Mary's Hospital for Women & Children, London etc.] & HAMILTON PATERSON J. L. [M.D. M.R.C.S., Pathologist Redhill County Hospital Edgware etc.] *Sternal Puncture. A Method of Clinical and Cytological Investigation.* With a Foreword by the Rt Hon. Lord HORDER, M.D. F.R.C.P. 3rd Edition. pp. xv+80 13 pls. (12 coloured) & 2 figs. 1946 London William Heinemann—Medical Books—Ltd. [15s.]

The procedure of sternal puncture as an aid in the diagnosis and study of abnormal conditions in the bone marrow is of recent origin but has proved so useful that it is now widely practised, and there is a considerable literature on the subject and on the applications of the technique.

The authors have attempted to supply medical practitioners with a concise handbook giving a short account of the main types of marrow derangement and their correlation with the blood picture in each case.

Chapter I gives a useful account of the normal myelogram which must form the background against which the changes found in the bone marrow in various pathological states must be considered and the account if over-concise is probably sufficient with regard to the scope of the whole work.

There follow eight chapters on various blood disorders with descriptions of the changes seen in the bone marrow a mass of material which cannot be dealt with in detail in a short review but on which a few general remarks are made below

The last chapter gives a description of the technique of sternal puncture with rather incongruously accounts of methods used for vital staining and dark ground illumination of the material obtained as well as an account of mitosis

The arrangement of the coloured plates opposite the letterpress they illustrate is good and the plates themselves are well reproduced with the possible exception of that illustrating the bone marrow in malaria, where the representation of gametocytes and schizonts would be of little help in their identification in an actual preparation

The treatment of the subject matter of the chapters on various pathological states of the bone marrow suffers from the limitations of the very *raison d'être* of such a book i.e. an attempt at condensation of material not easily condensed. As an extreme example of this Chapter III may be cited. The entire chapter the subject of which is Leukaemoid Reactions consists of 25 lines and two words. The vagueness of the statements in this chapter apart from its extreme brevity would defy attempts to extract useful information from it either by the student or the professional haematologist. Another drawback to the book probably due to the same cause is the omission of some conditions one would have expected to see included such as Cooley's anaemia or erythroblastic anaemia and among the protozoal diseases infections with *Trypanosoma cruzi*

Typographical errors are too numerous indicating hasty proof reading and there are other mistakes possibly due to the same cause. For instance on page 32 the use of the word chapters instead of sections is completely misleading. In the section on protozoal infections there are some misleading statements. It is stated for instance that liver puncture does not usually give very satisfactory material for examinations. This is the reverse of true for kala azar since the material obtained by sternal puncture may sometimes show very few parasites although these are numerous in the spleen or liver of the same patient

The index to the book can only be described as extremely incomplete and is of very little use for locating any particular subject dealt with in the text.

Apart from the defects pointed out above the book would appeal to the undergraduate student, who would find in it a review of the subject giving information which could only be obtained otherwise widely scattered in the literature on haematology but the specialist and the worker in the tropics would probably prefer to consult the originals from which it is condensed

H E Shortt

Roy D N [M D D T M Professor of Medical Entomology School of Tropical Medicine Calcutta] Entomology (Medical and Veterinary) pp vii + 358 162 figs. & 11 pls. 1946 Calcutta. Saraswati Library C18 & 19 College Street Market [Rs 30]

This volume is finely produced and illustrated and its general scope and arrangement at first sight suggest that it is well suited for the use of the medical officer in the tropics. Professor Roy is of course, fully qualified to write on Indian entomology and his account of certain aspects of his subject is excellent unfortunately however this standard is not fully maintained when dealing with arthropods whose importance is most marked in countries other than India.

The book is published in India but since no statement to the contrary is made, it is presumably also intended for workers outside that country. The

sub-title of the book indicates that the scope of the work is intended to cover veterinary as well as medical entomology, and indeed, the author states in his preface that the book was written "with the object of providing medical and veterinary students also public health workers with a treatise containing up-to-date information on the life history and bionomics of disease-carrying insects." This is a wide field and although the author does not separate the subjects the reviewer proposes, for the sake of clarity, to consider the veterinary and medical approaches separately.

So far as the veterinary aspect is concerned the reviewer is of the opinion that the information provided is usually inadequate for a serious student and that it is seldom up-to-date. To quote examples amongst the Diptera the part played by mosquitoes in the transmission of equine encephalomyelitis and Rift Valley Fever is not referred to—no description is given of the important part played by *Culicoides* in the transmission of filariasis to domestic stock and it is stated that *O. gibsoni* and other species of *Onchocerca* are possibly transmitted by *Simulium* (Cleland, 1927) (p. 177). *Eabronema muscae* is mentioned as a parasite of the house-fly (p. 185) but no mention is made of *H. megastoma* or of the fact that as a result of transmission by house-flies the adult forms of these helminths occur in equines. *Stomoxys* (p. 221) is referred to as a vector of surra, but no indication is given that it also transmits *H. microstoma* and *Setaria cervi* to domestic animals and *Hymenolepis cariosa* to domestic fowls. Calliphorine myiasis is of vast importance to students of veterinary medicine, but the subject is dismissed in a few lines, and no reference is made to causal factor or to control. The important genus *Hypoderma* (p. 218) is almost equally cursorily dealt with, and the short description contains many inaccuracies—thus. The larvae of *H. bovis* are large and of greenish brown colour whereas those of *H. lineatum* are smaller and brownish grey. The larval life of *H. lineatum* is also much shorter. The effect of the parasite *H. bovis* on cattle is very serious. The growth is inhibited and the production of milk is reduced. It is not known how the larvae find their way to the animal's back as the eggs are always laid on the lower parts." The account of the Mallophaga (p. 280) is inadequate and contains the somewhat misleading statement that the insects belonging to the order are generally parasites of birds and one genus *Trichodectes* is found on mammals. The statement (p. 300) that "The causative organism of Texas fever is *Babesia bovis* or *B. bigemina* (sic) and is transmitted by *B. annulatus* and *B. decoloratus* Koch" suggests the quite untenable view that *B. bovis* and *B. bigemina* are identical. Psoroptic mange is one of the most important subjects to be dealt with in veterinary entomology, but Dr. Roy dismisses it in some ten lines and these contain several inaccuracies—thus. Scabies or mange in cattle is a specific disease of the skin caused by *Psoroptes communis* var. *bovis*. In sheep *Otodectes* produce the same type of disease (p. 330).

As regards the value of the book from the medical aspect the situation is somewhat different. The Culicidae and the Muscidae and their relation to disease are adequately and clearly described, although there are many statements which require alteration or amendment. For instance when describing the method of immunization against yellow fever Dr. Roy writes (p. 130). "The person to be immunised is given a suspension of mouse-fixed yellow fever virus followed immediately by immune yellow fever serum from a recovered case of yellow fever or from a previously immunised person." This is obviously out of date and should be re-written. On page 52 it is stated that "In addition to malaria it is possible that some anophelines are capable of conveying the larvae of filariae by anophelines in India but their importance in Africa is omitted." Such generalized inaccuracies followed by subsequent corrections are not

uncommon. Thus it is surprising to find (p 244) that canine and infantile leishmaniasis are included amongst the diseases transmitted by fleas although previously (p 164) it is correctly stated that both diseases are transmitted by *Phlebotomus*. Again (p 215) *Cordylobia anthropophaga* is referred to as laying her eggs on the ground where there is smell of animal or human perspiration, followed by the statement that the life history is incompletely known. Yet on the next page reference is made to the paper by Blacklock and Thompson in which the life-cycle is completely described. Most unfortunately some gross inaccuracies remain uncorrected throughout the book. When describing the life-cycle of *Dermatobia hominis* Dr Roy writes as follows: The eggs are laid on leaves and branches of trees which become attached to the ventral surface of the abdomen of [the] mosquito which mechanically transfers the first stage larva contained in the egg to the skin of animals. Almost equally misleading is the statement that Its presence in man is indicated by a painless tumour on the skin. Similar types of inaccuracy are allowed to remain uncorrected when dealing with such an important vector of disease as *Trombicula* (pp 319-321) the description of which contains the following statements: Only two species are of medical importance as they transmit in their larval stages the virus of a typhus-like fever: these are *Trombicula akamushi* (Japan) and *T. deliensis* (Sumatra, Java and India). The larval *T. akamushi* Brumpt is decidedly more reddish in colour than the larval *T. deliensis* Walch.

Any transmission experimental work with *T. deliensis* is not easy. The adult mites of both sexes can be obtained often in large numbers from the ears of field rats.

There is evidence to suspect that other arthropods in addition to mites probably also act as vectors. However mites appear to be the most important transmitting agent known at the present time. On page 305 the only animal reservoir given for *Rickettsia orientalis* is the bandicoot. This statement is correctly copied from a short paragraph which appeared in the *Lancet* of January 31st 1942 but the error has frequently been corrected in more recent articles on the subject.

The reviewer has pointed out these shortcomings and discrepancies not with a view to destructive criticism but in order to show that the book in its present form does not fulfill its avowed object of providing up-to-date information on the life-history and bionomics of disease-carrying insects. If the book were confined to medical entomology and if those portions of it which deal with aspects of the subject outside India were brought to the same standard of excellence as is reached in the description of the Indian culicidae the work would fulfil a useful purpose.

As already stated the general production and illustrating are excellent but proof-reading has been insufficient and many typographical errors and mis-spellings remain uncorrected.

R. M. Gordon

TOUMANOFF C. [Docteur ès Sciences (Sorbonne) Chef du Service d'Entomologie médicale aux Instituts Pasteur de l'Indochine] *Les Tiques (Ixodidae) de l'Indochine. Recherches faunistiques avec indications sur les Ixodidae des pays voisins. Notions générales sur la biologie et les moyens de combattre ces Acariens.* [The Ticks of Indo-China. Biology and Methods of Control.] pp II+220 94 pls. [Bibliography] 1944. Saigon: Institut Pasteur de l'Indochine.

In 1924 the Government of Cochinchina instituted the Laboratoire d'Entomologie et d'Hygiène the primary work of which was directed towards the study of the mosquito vectors of malaria and other diseases of man and animals. Since the opening of the laboratory the staff have already published two monographs on mosquitoes the first by BOREL in 1930 [this *Bulletin*

1931 v 28 335] and the second by TOUMANOFF in 1936 [*ibid* 1937 v 34 517]. The activities of the laboratory have however also included the study of various other arthropods of medical and veterinary importance and, in addition to the present monograph on ticks studies on fleas in relation to plague and the rôle of tabanid and other flies in relation to surra are in process of completion.

Dr Toumanoff divides his work into five parts. The first is devoted to the technique employed for collecting, preserving and examining the material. These methods conform to the usual standards but the author refers to his lack of success when collecting ticks from herbage by drawing a flannel cloth over the area. For observing the morphology of the tick by direct illumination the author describes and figures a simple viewing board, which can be attached to the mechanical stage of the microscope and which is grooved in two directions in order to receive a circular glass disk, to the centre of which the tick is temporarily attached. The remainder of the first part of the monograph consists of a brief but admirably clear description of the external anatomy of the Ixodidae, the terms used for the various parts and the classification adopted. Dr Toumanoff has accepted the general classification of Neveu-Lemaire in what is referred to as his recent work (it was published in 1939) but for defining the characters in each group he has followed Aragão and, mainly for genera not referred to by Aragão, Brumpt.

The bulk of the work—some 118 pages out of a total of 200—is devoted to a systematic description of the ticks recorded from Indo-China of which the author describes 39 species in the family Ixodidae and two in the family Argasidae. Of the latter only *Argas respirationis*, a parasite of bats, has been found by the author although *A. persicus* is said to occur in the Far East. In the reviewer's opinion the value of a systematic description can be estimated only when in use as a key, that is to say when it is studied in conjunction with the actual specimens being described. Nevertheless the description of each of these 41 species is not only concisely given but is also accompanied by admirably clear and well-printed plates and text figures so that there seems little doubt that when this text is applied, all who are concerned with the identification of the ticks will be indebted to Dr Toumanoff.

The third part of the monograph is concerned, first with the general biology of the ticks and later with more detailed references to certain important genera and species.

In his introduction the author truly states that the study of the ticks affecting man and animals should be based on similar lines to those which have afforded invaluable information concerning the relationship of various species of *Anopheles* to malaria—a point too often forgotten particularly in veterinary medicine where sometimes little distinction is drawn between "a vector" and an important vector. In the fourth part of his monograph Dr Toumanoff deals generally with the rôle of ticks as transmitters of disease including in his account certain diseases such as tick-borne relapsing fever which have not been recorded in Indo-China.

The fifth and final section is concerned with control. The subject is dealt with generally with particular emphasis on the control of *Boophilus annulatus* var. *australis* in Cochin China. This part of the work and the sub-section devoted to personal prophylaxis although sound and interesting contain nothing new. The monograph ends with a short review of the natural enemies of the tick and their utilization in control.

In his foreword the author refers to his monograph as "a modest contribution to the subject of medical entomology in Indo-China." All workers in medical and veterinary entomology will place a higher value on this work, and will consider it a valuable contribution to an important subject.

It is unfortunate that in a volume otherwise so well presented the stitching and outer covering should be of so poor a quality

PAMPANA, Emilio *Epidemiologia della malaria. Studi di Medicina e Biologia* [The Epidemiology of Malaria.] 403 pp 92 figs & 2 folding pls 1944
 Rome Editrice Nazionale [L480]

This comprehensive text book on the epidemiology of malaria presupposes in the reader a fundamental knowledge of the clinical manifestations pathology and parasitology of the disease. It contains clear and concise accounts of the endemic and epidemic phenomena that characterize malaria in all parts of the world and few if any important contributions to our knowledge of the epidemiology of the disease have escaped the author's attention. To bring together so much miscellaneous material and to build it up into a coherent very readable treatise is a difficult task that the author has accomplished with distinction. Each chapter has an adequate list of references to the literature. Subjects treated include characteristics of malaria infection and the cycle of its transmission distribution of malaria in space and time climatic telluric and socio-economic factors in the epidemiology of malaria various forms of endemic malaria epidemic endemic and hyperendemic malaria anophelism without malaria and regression of malaria and a wealth of information concerned with the carrying out of a malaria survey.

The book was produced in difficult conditions and *errata* are unduly numerous but these are but small blemishes to an otherwise admirable volume

Norman White

DOELEMAN H *De malaria-epidemie te Middelburg in de jaren 1940 tot en met 1945, benevens een onderzoek van parasietendragers.* [The Malaria Epidemic at Middelburg 1940-1945 and Parasite-Carriers] [Thesis for Doctorate of Medicine Univ of Leiden.] 138 pp 6 plans on double pls & 2 graphs [Bibliography] English summary 1946 Goes Oosterbaan & Le Cointre NV

The freshness of a published doctorate thesis with its reminder of how a subject has reached current maturity is often one of its main attractions. Dr Doeleman saw his first malaria patient in 1940 and as a student at Utrecht had never heard of malaria except as a tropical disease which was said to occur also in some places in Holland. Middelburg the seat of his investigations on Walcheren is the capital of the province of Zeeland and has earned fame or notoriety not only in the recent war but in days gone by. During the stay of the English ambassador Cuthbert Tonstal at the Spanish court in 1517 the Zeeland fevers were greatly dreaded and drew from him the comment that no one left the province without disablement. He thought that the Styx and the Acheron rivers of Hell, must be situated close to this coast. An epidemic in the English Expeditionary Force which landed on Walcheren in 1809 and which was based upon Middelburg reduced that force from 40 000 to 15 000 men. Drainage and agriculture in South Holland just as in Scotland 200 years ago banished epidemic malaria. Zeeland was freed from epidemic malaria by the beginning of this century. The Zeeland fevers however were not all malarial. Among them were included typhus, the typhoid fevers and the dysenteries. Intermittent fevers and bilious fevers were not differentially diagnosed in the days when thermometers were not used and there were no laboratory investigations. The malaria parasite was demonstrated by the apothecary Van der Harst in 1900 a year in which Berdenus van Berlekom Jr described an epidemic at Middelburg.

Dr Doeleman follows his excellent first chapter on the history of malaria in Zeeland with four more chapters which cover systematically the epidemic and its control—investigation of parasite carriers, the principles of the campaign and epidemiological notes. Much of the information on the nature of the intermittent fevers of Zeeland has been culled from articles by Honig and Swellengrebel (this *Bulletin* 1927 v. 24: 344) and due recognition is accorded to the first report by Schouten of the Malaria Commission of the Department of Health in 1920. It is to van Thiel personally that Doeleman expresses his thanks for support and with his name are coupled those of other members of this Commission: Schuffner, Swellengrebel and de Buck. Hulshoff Pol is another of the authors to whose investigations Doeleman pays tribute. From the views promulgated by these authorities and from his own researches Doeleman argues especially that the "healthy" parasite-carrier is the important and dangerous factor in the carry-over of malaria from the preceding autumnal months to the relapses in April and May of the following year—that the disappearance of parasites on clinical examinations of those who have been given courses of quinine in autumn does not necessarily denote complete eradication—that fresh infection takes place beginning in July and August and reaching its height in the autumn months—that healthy carriers do not sacrifice their premunition, or symptomless equilibrium between parasite and host by treatment with quinine and so on. Some of these features may be referred to in more detail according to the successive chapters.

In chapter II on the Description of the Epidemic and its Control we have the record of the author's own investigations and activity from 1942 onwards. He concentrated upon Middelburg where malaria had shown signs of increase in 1940. It would seem that the author is not disposed to blame the bombardment of Middelburg in 1940 with ruin of the town and development of mosquito breeding places in the cellars as more than merely one factor in the epidemic intensification; nor yet is he prepared to maintain that the inundation of Walcheren and the evacuation (11.9.44) of the people from the island banished malaria for the time being. Most of the inhabitants of Middelburg did not leave the town. The subject of relapse receives special attention—a factor which according to Korteweg is the crux of what is otherwise benign tertian malaria. A reference is made to the zoophilism of mosquitoes and to the finding of 20 000 *Anopheles* in abandoned horse stables. This is also referred to elsewhere and animals other than the horse are implicated, namely even pigs, rabbits and poultry.

For control Doeleman—while he does not in any way deprecate the value of work done on the breeding places of mosquitoes and the outhouses of human habitations—prefers to concentrate upon therapeutic measures designed to rid not only the human malaria patient but also and especially the dangerous healthy parasite-carrier of his plasmodia, and upon the detection of relapse cases. All methods of detection must be vigorously employed, blood examination, spleen examination and the like. As measures of prevention he recommends the spraying of houses in which malaria cases had occurred, with Shelltox, now likely to be superseded by DDT—and the autumnal administration of quinine to the malaria patients of the previous year in doses of 1 gm. of sulphate of quinine twice weekly on two successive days from mid August to the end of October—that is for a period of 8 weeks. It is to be noted that only quinine was available at this time. He does not minimize however the fact that this is a counsel of perfection which takes no account of the ineffectiveness of spraying apparatus or the difficulty that confronts a practitioner in persuading a person who is "healthy" and uncomplaining, to take a long and regular course of quinine.

In chapter III the investigation of parasite carriers is specifically dealt with. These are not restricted to children as they seem to be in tropical lands (by which is probably meant hyperendemic regions) in Holland—where less malaria prevails—carriers are distributed among persons of varying age. If malaria is really to be prevented altogether there must be efficient treatment of every infected person not only the malaria patient but also the healthy parasite carrier. The question of development of immunity is raised in order to stress the concept of 'premunition' as defined by Sergent which, as a latent infection and an equilibrium toleration of parasite by the host is compared with the allergic conditions of symptomless latency in tuberculosis and syphilis. Disappearance of parasites from the peripheral blood is well known and has been described as a retreat only to the spleen or more correctly to the reticulo-endothelial system.

Chapter IV treats of the principles of campaigning against malaria. The importance of this section lies in its insistence on the difference between the ideal and the practical. Doeleman seems to consider that the length of the course of quinine had no demonstrable influence on relapses and that a week's course of 1 gm. of quinine each day was economical practicable and within the disciplinary power of the practitioner. In the second place a knowledge of the bionomics of the mosquito and the time of the infectiveness of the *Anopheles* would save much futile effort. Thus to mention one example only the Dutch investigators have shown how much of the malaria of Holland is due to *Anopheles maculipennis atroparvus* breeding in brackish water and how little if any is due to *messeae* which breeds in fresh water. The spraying campaign requires 0.4 to 0.5 litres of Shelltox per house and the house remains for some 14 days repellent to incoming *Anopheles* after which spraying must be repeated.

In his last chapter are various notes referring to malaria statistics to the question whether malaria in Middelburg is endemic or epidemic, with the conclusion that it is endemic and that an epidemic is only an exacerbation to the influence of live-stock on the persistence of malaria to the prognosis of malaria in Walcheren, as reclamation of its inundation devastation proceeds and it includes a short note on the problematical danger of therapeutic malaria infection in the treatment of dementia paralytica.

A hope is expressed by the author that his observations in Middelburg may be helpful to others faced with similar problems throughout Holland and we think that perusal of this monograph would undoubtedly be of great service.

MAGOON, E. H. [M.S. in San Eng. D. Eng. etc.] *Drainage for Health in the Caribbean Area*. [Spanish translation by J. A. HERNANDEZ C.E.] 556 pp. 80 pls. [Reprinted from Boletín Oficial Salubridad y Asistencia Social 1945 Feb-Oct v. 48 Nos. 2-10]

The business of malaria control has reached a higher stage of development in the Americas than in many parts of the Old World and there have grown up several classes of skilled people engaged in it. There is the technical specialist to describe whom we only have the ugly word malarialogist who is responsible for the general direction of policy and the preparation of schemes. There is a large class of malaria engineers specially skilled and practised in those branches of civil engineering on which malaria control may depend. There is also a group akin to our Sanitary Inspector and under him a large class of skilled artisans normally engaged in anti-malarial works and having some special knowledge of the problems particular to them.

This book is intended for the instruction of all of these groups except the first but mainly for the malaria engineer and the sanitary inspector. It gives

In the second part of this work, similar analyses are given of the oils derived from *Hydnocarpus wrightiana* and *H. anthelmintica* which have been grown in the Belgian Congo. They show high content of hydnocarpic acid, low proportions of chaulmoogric acid—the first contains 12 per cent. of goicic acid, but the second very little. Among the conclusions are that both *C. urehitchensis* and *L. dentata* should furnish esters and sodium salts and that their fractions especially the lower melting point hydnocarpic acid fraction are well worthy of trial in the treatment of leprosy. This memoir is a valuable one which should be consulted by all interested in the chemical composition of chaulmoogra oils as a class in relation to their use in the treatment of leprosy.

L. Rogers

Pozzo Adolfo. Peste de Oriente. Oriental Plague.] Prologos de los Profesores Carlos Fonso GANDOLFO & Carlos E. PAZ SOLDÁN. 299 pp., 77 figs. Bibliography. 1945. Buenos Aires. Editorial Alfa," San Martin 693.

This systematic book on plague in paper covers should become a standard not only for the plague worker but for the practitioner. It has special importance naturally for Spanish South America and Brazil, and has detailed reference to Argentina. All aspects of plague are dealt with, beginning with biblical history and passing on to the history of its introduction into the New World. The date of arrival at Monte Video in 1699 of the Dutch cargo boat *El Zier* from India is one which is generally accepted as the beginning of plague in South America and the whole historical subject is dealt with in the first 42 pages. Formal reference chapters on Bacteriology, Symptomatology and Pathological Anatomy follow and bring us to the important subject of Sylvatic Plague. An illuminating analysis is given of the spread of plague in its stages from the port to the towns and cities by the railway system from railway stations to the country and then further into the country largely as sylvatic plague. The author objects to the term sylvatic as insufficiently descriptive, and would use the term rural as the antithesis to port or urban plague. As the argument on sylvatic plague develops it seems evident that the main factor contributing to epidemic human plague is still the rat although field and semi-domestic rodents do contribute in a reverse direction to initiate rat epizootics. This is a very important contention because it suggests that anti-plague measures against rodents must, for economic reasons if no other, concentrate upon the rat. Under present conditions it is hopeless and indeed impossible to deal effectively with the sylvatic rodent on a country-wide basis. Fortunately the danger of direct human infection from this source is more or less accidental and is likely to be confined to children or individuals who would utilize the pelt of a dead or sick animal. Prevention of such happenings can be effective up to a point by propaganda and by warning of this danger. Rat proofing and rat annihilation are the preventive measures *par excellence* so far as rodents are concerned. In the Argentine certain of the field rodents some of them semi-domestic, are singled out for special reference. These are the Cuis (*Microcavia australis australis*) and Graomys (*Graomys griseoflavus griseoflavus*). Good illustrations are given of these as well as of the plague rats *R. norvegicus*, *R. rattus rattus* and *R. rattus alexandrinus*. Many photographs of places and procedure illustrate the text. Line drawings of the differences between the fleas *Pulex nosopsyllus*, *Xenopsylla Ctenocephalus*, *Leptopsylla* and *Ropalopsyllus* based on head, thorax and abdominal characters should prove useful. Other line drawings are of the "blocked" flea and of the distinctive features of the various species of the genus *Xenopsylla*—*chopsis brasiliensis* and *asia*. The extensive bibliography would make a good foundation for a card-index to literature and has the great merit of giving the titles

of the papers as well as details of the publication. The work can be heartily recommended as sound and serviceable and especially Seneca's aphorism with which the text concludes —

Longum iter est per praecepta breve et efficax per exempla H. F. Harvey

AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE. PUBLICATION No 18 Washington D.C. 1942. 130 pp. numerous illustrations. A Symposium on Relapsing Fever in the Americas. [Edited by Forest Ray Moulton] [19s.]

The American Association for the Advancement of Science unlike its British counterpart embraces the applications of science in medicine and public health and in recent years has published a series of volumes on important public health problems based on symposia arranged by the Section on Medical Sciences. Relapsing Fever in the Americas is the eighth of these volumes and comprises a series of papers presented at a symposium held in December 1941 at the Dallas Texas meeting of the Association. The 23 contributors represent workers in very different branches of the subject and their papers are grouped together under seven headings — introduction distribution parasitology tick vectors epidemiology symptomatology and public health aspects.

The historical introduction includes interesting notes on the life of Obermeier whose discovery of the spirochaete of European relapsing fever in 1868 opened a new chapter in scientific medicine since in his day bacteria had not yet been specifically associated with human disease. His death took place when only 30 years old as the result of injecting himself with blood from a moribund cholera patient in the hope of elucidating the cause of the malady.

The present distribution of relapsing fever in Oklahoma California, Texas and Panama respectively forms the subject of four contributions and although comparatively few cases are recorded conclusive evidence is brought forward in support of the view that the infection is widespread in the animal population especially burrowing rodents. The vexed question of taxonomy is dealt with by H. G. JOHNSTONE who adopts WENYON'S proposal that the generic name *Traponema* should be used for spirochaetes both of the blood and of tissue. With reference to the specific name all relapsing fever spirochaetes are considered to constitute one species *T. recurrentis*. It is suggested that each different type might be designated by its geographical locality and specific intermediate arthropod host e.g. *T. recurrentis* California *Ornithodoros hermsi* strain or the *O. turicata* strain of *T. recurrentis* Mexico.

The unity or plurality of species is discussed by Gordon E. DAVIS who gives results obtained with three local (U.S.A.) vectors and their respective spirochaetes and with exotic species of ticks supporting the view that host-specific relationship offers the most accurate approach to the subject. Useful technical details are summarized in the section on laboratory diagnosis and cultivation of the spirochaetes which is followed by a discussion of the very complex problem of the relapse phenomenon in this disease. It is suggested by SCHUBART that the variable number of relapses (1 to 12) in tick-borne relapsing fever may be best explained in terms of the large number of possible antigenic phases, the number of these involved in each attack and relapse and the continuing capacity of the spirochaetes to produce new antigenic variants.

The article on tick vectors and life-cycles by Gordon E. DAVIS summarizes information on 25 American species of *Ornithodoros* of which only 5 are proved vectors to man. In addition R. A. COOLEY summarizes the specific characters and distribution of all known species of the genus a total of 44. E. FRANCIS

of labour migration from Ruanda across the Belgian border. In addition the effect of war conditions on African labour was investigated and the whole subject was discussed with the Governments concerned."

In general the African is a farmer cultivating for the maintenance of his family a portion of the tribal land of his village but not owning the land. The work is shared by all the members of his household and he is largely independent of wages. His needs are few and simple and it is only when his crops fail through drought or other uncontrollable cause that he is compelled to go to work for wages. He can ordinarily leave his family for months confident that they will not starve and will be protected by tribal ties and obligations. With a special object usually to gain a certain amount of money he travels long distances—hundreds of miles—to work on sisal estates or plantations etc. Higher wages instead of attracting him to stay longer merely enable him to leave earlier with the sum of money aimed at.

The author deals with labour conditions in relation to this background such matters as the welfare of Africans employed on large estates or by Government Departments including accommodation for families provision of hospitals and schools and social amenities questions of compensation for injury and illness trade unions the provision of camps on travel routes precautions against the spread of disease and many other important questions are discussed.

The needs of war produced some new industries and expanded existing ones factories for textiles leather goods dried vegetables dried milk timber production etc. were successfully developed, and the production of rubber pyrethrum and sisal was increased.

Occupational training the relationship of clerical and technical education to each other domestic training for girls juvenile labour especially in towns are important questions dealt with in this report.

The author shows the need for the establishment of properly equipped and staffed Labour Departments in these colonies and suggests how they should be constituted. The Head should be a Labour Commissioner with a seat on Council under him there would be Deputy Commissioners a Medical Officer a Trade Union Officer and Labour Officers. The problems that will arise in the future make it necessary to appoint men with special knowledge of their branches.

Conscription of labour and the immigration from Ruanda Urundi are discussed.

The Report is a most interesting one and will be of great value to all who may be concerned in the development of East Africa and the welfare of its inhabitants.

HONIG Pieter [Ph.D. etc.] & VERDOORN Frans [Ph.D.] [Edited by] Sciences and Scientists in the Netherlands Indies. *Natuurwetenschappelijk Tijdschr. v. Nederl. Indië* 1945 Vol. 102. Special Suppl. 491 pp. 134 figs & 1 folding map. New York City. Board for the Netherlands Indies Surinam and Curaçao.

This extensive symposium of articles on all branches of science was collected by the Board for the Netherlands Indies and provides a summary of great historical interest. For the medical reader the chapters on the history of cinchona the relation between soil and population density rabies research, medical contributions from the Netherlands Indies and medical education, will be of most interest. These chapters form a small proportion of the mass of information on many diverse subjects of scientific interest the contributors to this volume are eminent in the subjects with which they deal.

COMPOSITION OF MOSQUITO LARVICIDES

By G MACDONALD M.D. D.P.H. D.T.M.

*Professor of Tropical Hygiene London School of Hygiene and Tropical Medicine
Director of the Ross Institute*

A very large number of substances have been used as mosquito larvicides but only a few are or are likely to be in general use. They may be classified according to whether they are applied as surface films as floating powders, or in suspension or solution. Only those in the first category are generally useful under all circumstances though Paris green in the second has had big advantages in special conditions. With the introduction of DDT surface film larvicides are likely again to be the most widely used. A preliminary understanding of the properties of films is essential to their proper selection and use.

Oil Films

An oil film whether used as a direct larvicide or as a vehicle for another such as DDT must have certain qualities of spreading power and stability and if used alone it must also be toxic to larvae. The spreading pressure expressed in dynes per cm. is a measure of the force exerted by a film to overcome resistance to its spread. In the case for instance of highly purified medicinal paraffin it is 0 dynes/cm. and the paraffin will not spread even on an entirely clean surface. Kerosene usually has a value of about 10 dynes/cm. gas oils of 13 to 16 dynes/cm. and they will spread on many moderately clean surfaces but are often prevented from doing so by naturally occurring surface contaminations. A good larvicidal oil for general purposes should have a spreading pressure of not less than 23 dynes/cm. and if self-spreading sufficient to penetrate deeply amongst vegetation and against most naturally occurring obstacles is needed oils with very high spreading pressures of the order of 46 dynes/cm. should be used.

ADAM (1945) has described a simple field method for the estimation of spreading pressure by opposing successive members of a series of oils with known spreading pressures against the unknown oil on a clean water surface by which means it is possible to find the place of the unknown in the known series. The test needs few and simple materials and apparatus: terpeneol technical quality, oleyl alcohol, pure medicinal paraffin, an 8-inch glass funnel retort stands and running water and can be carried out in a very primitive laboratory. The main details are excerpted in this *Bulletin* 1946 v 43 255.

The spreading pressure of natural oils is largely dependent on the presence of impurities exerting surface action and it can be reinforced by the addition of spread-aids. Vegetable oils and fatty acids such as crude castor oil

(1-2 per cent) and oleic acid (0.5 per cent) are commonly used for this purpose but have the disadvantage that they decrease the stability of the films. Ceryllic acid is without this disadvantage and may usefully be added in proportions of 0.25 to 1.5 per cent. Commercial resin is a good spread-aid; a concentration of 0.25 per cent greatly raising the spreading pressure, though it has the disadvantage that it is difficult to dissolve. In the process of refining oil the spread-aiding substances tend to be concentrated in some of the by-products which are then used to increase the spreading pressure of special larvicidal oils which, on the whole, are of good quality. In no case should substances soluble in water such as phenols or saponated cresol, be used, as the action is quickly reversed and soon results in a decreased spread.

MURRAY (1938) has shown that the stability of films is in part due to the qualities of the hydrocarbons constituting the oil and in part due to dissolved polar substances some of which increase and some of which decrease the permanence of the film. To secure maximum stability the oil should consist of a mixture of wide and overlapping cuts with either very high or very low aromatic content and should not contain fats or fatty acids as spread-aids. This quality can best be judged by an empirical field test applying the oil under natural conditions on a windless day and rejecting any specimen which does not form a stable film lasting at least two hours.

Oils appear to vary very much in their toxicity to larvae but in reality they vary more in rapidity than in certainty of action. MURRAY (1936) has shown that once oil enters the tracheal system, the ultimate death of the larva is almost inevitable but may occur in a few minutes or be delayed until pupation is due. The best penetration is secured with oils of medium (200-300°C) boiling range and highly volatile substances may have an irritating effect which causes the larva to avoid contact and so to escape destruction. In testing oils for this quality a film 10 microns thick (1 cc to 1 000 sq. cm) should be spread on the surface of water in which there are about 50 larvae. After 30 minutes the larvae should be removed without being artificially contaminated preferably after the water surface has been cleansed by allowing the receptacle to overflow and the death rate should be recorded at the end of one hour from the beginning of the test in which time a good oil should kill all larvae.

When oil alone is used as a larvicide the object is to spread a film not less than 10 microns thick, which corresponds to 14 gallons per acre or 0.3 gallons per 1,000 sq. ft. though in practice larger quantities up to 25 gallons per acre are commonly used. With the type of oil normally used with a spreading pressure of about 23 dynes/cm. a film can be expected to form, but deep penetration against natural films cannot be relied on. The oil must be sprayed over the entire water surface where larvae may occur. Substitutes such as drip-cans and oil-balls may work under some circumstances, but are very unreliable.

DDT Solutions.

DDT applied in solution as a surface film, has a minimum practical lethal dose of the order of 10 mgm. per sq. metre i.e. 1.43 oz. (or 1.43 pints of 5 per cent solution) per acre though the dose applied is usually greater than this of the order of 4 pints per acre. Larvae are killed fairly rapidly and first instar larvae re-appear in a few days but the number of larvae (particularly of fully grown ones) remains subnormal for a period which may be as long as a month. Apart from this rather unreliable effect there is no residual action comparable with that exerted when DDT is applied as an adult insecticide and it seems that the DDT is removed from the water through a physical effect of the bottom mud complex and of suspended material (ARNOLD

FERGUSON and UPHOLT 1945) Conversely UPHOLT GAINES SIMMONS and ARNOLD (1945) have shown that a very prolonged residual effect is exerted in water free from mud such as the containers commonly accepted as breeding places by *Aedes aegypti* and that its use on this type of water may revolutionize *Aedes* control

Several workers have shown that effective spread of DDT solutions occurs from the point of application and RIBBANDS (1945) has recommended the abandonment of the usual spraying technique and the substitution of discrete applications from an oil can or similar means In his trials doses of 4 cc. of 5 per cent solution produced a complete kill for a minimum distance of 25 ft. along the bank from the place of application and in one case for 70 ft despite the presence of moderate vegetation He found that oils commonly used were quite effective for this purpose but the reviewer has had failures of spread on still waters in Iran and advocates the use of specially prepared oils with really high spreading pressures over 46 dynes/cm for this purpose. In one of his trials of a 5 per cent solution of DDT in a specially prepared oil eight discrete applications of 65 cc. destroyed all larvae in 4 000 linear feet of stagnant irrigation channels containing moderate vegetation the total area treated being 16,250 sq ft and the overall dose 2.5 pints per acre. Solutions in other oils applied to very similar waters failed to penetrate natural obstacles and left many living larvae

If the full advantage of DDT is to be utilized, this method of discrete application must replace spraying Much experience with it is to be gained before the technique can be accurately laid down but as a working basis for extensive trial it is suggested that a 5 per cent solution of DDT in a stable oil with a spreading pressure of not less than 46 dynes/cm. should be used, and that on still water it should be applied in individual doses of about 2 oz. which should be sufficient to destroy larvae over an area of about 2 000 sq ft (the area of a circle of radius 25 ft) from the point of application

During the war there has been a very rapid development in the distribution of DDT solutions from aircraft The strength of solution the solvent and the dose are much the same as in the case of ground application Various types of apparatus have been used in the simplest the stream of solution leaving a controlled outlet is shattered into a mist by the violence of the air current it meets on emergence in others the solution is discharged into the exhaust and a fine aerosol is thereby produced Designs of apparatus have been developed in the normal secrecy of war and the reviewer does not know of a published description of the type he considers suitable With most techniques the lethal swathe is about 200 ft. broad As one ton of solution is sufficient for 450 acres or for a 200-ft. swathe some 18 miles long very large areas can be quickly and effectively treated with the additional advantage that such of the solution as falls on vegetation serves as a residual insecticide to destroy ovipositing adults there is immediately a great reduction in mosquito density—a point emphasized in the work of LINDQUIST and McDUFFIE (1945) The cost of maintenance of aircraft of the types commonly used in the war is so high that the techniques cannot be widely used in peace time though apparatus for smaller aircraft may be developed for the treatment of large water areas.

Floating Powders

Floating powders as larvicides were first advocated to take advantage of the special feeding habits of anopheline larvae which skim minute particles from the surface For this reason the powders are destructive to anophelines only and are generally useless in moving water from which they may disappear before being ingested Paris green has become recognized as the most

generally suitable of such larvicides though many others such as copper cyanide copper arsenite and calcium arsenite have been quite extensively used. Pure paris green contains 56.6 per cent. of arsenic as As_2O_3 and commercial samples should contain nearly this amount preferably over 53 per cent and certainly never less than 50 per cent. The particle size is important as only the smaller particles are ingested. METCALF and HESS (1944) showed that the average maximum sizes of particles ingested by *Anopheles quadrimaculatus* larvae were 29 51 68 and 106 microns for 1st 2nd 3rd and 4th instar larvae. It is usual to specify that all the paris green should pass through a 200-mesh bolting cloth and that it should leave very little residue on a 300-mesh bolting cloth. Paris green answering such a specification contains many particles of excessive size and most of the particles may be too large for ingestion by 1st stage larvae. better results may be secured with very finely powdered preparations in which most of the particles are about 2 microns in diameter. For aircraft distribution, however very finely divided paris green is too liable to be drifted away by gentle breezes and a slightly coarser material is required. Metcalf and Hess recommended a quality in which 84 per cent. of the particles were between 20 and 50 microns in diameter. As there may be other unappreciated factors which affect its utility, it is usual to specify that samples should be submitted for laboratory trials to verify their lethal effect.

It is very difficult to assess the minimum lethal dose of paris green owing to the difficulty of ensuring complete and even distribution of minute quantities. With a product of good quality carefully and evenly distributed by a skilled worker a complete kill can be obtained with doses of about 4 oz. per acre but this is so wasteful of time that in practice a dose of 1 lb. per acre, which allows for some irregularity of distribution is now commonly accepted.

The whole trend of practice has been to emphasize the importance of simplicity of technique and the advantages of hand distribution over the use of mechanical sprayers in the treatment of all water except extensive swamps and even in the latter case the simpler technique should be used unless the labour is highly skilled. For hand distribution the strength of the mixture should be 1 per cent. and any dry dust or powder may be used as a diluent the mixture being made in a bucket with the aid of two measures to hold 1 oz. of paris green and 99 oz. of dust respectively and a wooden stick as a mixer. The mixture is then scattered by hand one normal handful being adequate to treat a circle of 4 ft. radius.

Where the extent of the water to be treated makes the use of mechanical "dust guns" inevitable a 5 per cent. dilution of paris green in some extremely fine powder preferably powdered soapstone or soft stone should be used, the mixture being made if possible in a cement mixer at some central site and distributed ready mixed to the place of application. It has been common to use a 33 per cent. mixture for aircraft distribution but when this is indicated, DDT has such manifest advantages that the use of paris green will probably now come to an end.

Emulsions and Suspensions

A number of substances have been used in emulsion form as larvicides phenol in the original Panama larvicide creosol, pyrethrum and now DDT. None of them has permanently established itself for general use and probably none will. In the case of DDT the tendency has been to make a 5 per cent. solution in fuel oil and to emulsify this with an emulsifying-spreading agent (unfortunately always described under a proprietary title) in about 30 times its volume of water thereby producing a larvicide to be used in doses comparable with the dose of oil—15 to 25 gallons per acre. The method may

save some of the material cost of oil it saves none of the labour which is the chief cost of oil distribution and self spreading such as described for DDT surface films cannot be relied on. The method may be of special use in the treatment of minute breeding places such as those of *Aedes* where applications of oil solutions of DDT might be very wasteful in which case the dose is arranged to secure a final dilution of about one part DDT per million parts of water.

When liquid based paris green was introduced by BARBER RICE and MANDEKOS (1936) it was carried in the oil phase of a kerosene water emulsion and was particularly suitable for the treatment of small breeding places including those in which the water was running. AZIZ (1939) later developed the use of plain suspensions of paris green in water and until the introduction of DDT this remained the most effective method for the treatment of shallow moving water in places where transport difficulties made the carriage of oil impossible or unduly expensive. The paris green which should be of normal grade and not the extremely fine grade referred to above is mixed with water in the spraying machine from which it is to be applied, in sufficient quantity to give a 1 in 500 or 1 in 250 suspension which is kept evenly mixed by occasional agitation of the machine. It is sprayed on the breeding place in sufficient quantity to give a minimum of 1 part or preferably 1.5 parts of paris green per million of water that is for a 1/500 suspension sprayed on water 3 inches deep one gallon to 870 sq ft. It has proved itself of exceptional value in the treatment of the shingly streams commonly used as breeding places by *Anopheles superpictus* in the Mediterranean area though recent experience suggests that DDT solutions may largely replace it.

Each of the larvicides described has some special qualities which make it more or less suitable for use for different kinds of breeding places or in different circumstances and each of them will probably remain in wide use. In any one scheme of mosquito control it is desirable to use the minimum possible number of methods and preferably one method only. To this end the method which is most generally suitable for the common conditions locally encountered should be chosen and adapted to as many of the local conditions as possible even though it may not theoretically be the most desirable for all of them. Only by this selection of methods can the proper training of subordinate labour on whom success finally depends be secured and the occasional use of a method which may not locally be the most economical is preferable to the confusion which arises when a choice of methods is left to men unqualified to make it.

SUMMARY OF RECENT ABSTRACTS.*

VIII TYPHUS GROUP OF FEVERS.

General.

GEAR (p. 362) gives an account of the rickettsial diseases of South Africa. Louse- flea and tick typhus are widespread, and the last can usually be distinguished from the other two clinically and by the Weil Felix reaction.

WOLSTENHOLME and GEAR (p. 877) discuss the various serological tests used in the differentiation of fevers of the typhus group. Most reliance is placed, for various reasons on the complement fixation reaction but as pointed out by MEGAW in comment this test does not always distinguish epidemic from murine typhus though it is usually effective in the diagnosis of the tick-borne group. [See also PLOTZ *et al.* below]

BENGTSON (p. 983) sums up the experience of the complement fixation test in the rickettsial diseases. She thinks it highly specific it can be used in retrospective diagnosis and in rats, and may become a routine procedure complementary to the Weil Felix reaction.

FITZPATRICK (p. 982) reports a study of the rickettsia agglutination test in the diagnosis and differential diagnosis of epidemic and murine typhus and Rocky Mountain spotted fever. The test is capable of distinguishing between epidemic and murine typhus usually by a difference in titre of the reaction to the two antigens. Differentiation of these from Rocky Mountain fever is more clear-cut. Details should be sought in the original abstract.

BLANC and BALTAZARD (p. 714) have carried out extensive research into the question of immunity in fevers of the typhus group. A frank attack of epidemic or of murine typhus immunizes against both infections for at least several years. Rocky Mountain spotted fever and boutonneuse fever also immunize against each other. Inapparent infection produces immunity and inapparent reinfection must be very rare. Hereditary transmission of infection in ticks readily explains persistence of the tick borne fevers but this does not occur in lice or fleas. The same authors (p. 715) state that of the two groups of typhus fevers louse-borne and flea borne on the one hand, and tick borne on the other neither can be transmitted by the vectors of the other. Murine rickettsiae can however be transmitted by lice from man to man. They do not think that inapparent attacks are important in maintaining louse-borne typhus during inter-epidemic periods but think that infection from dried, infected louse faeces is the cause of sporadic attacks and may initiate epidemics. Infected louse faeces are quickly inactivated by moisture and sterilization of clothing by steam is reliable. Louse control, by itself, is inadequate as a means of checking epidemics.

EYER and RUKA (p. 23) have studied the morphology of rickettsiae by means of the electron microscope.

DARZINS (p. 544) describes a method of staining rickettsiae details of which should be sought in the original abstract.

Incubation.

SCHULTEN (p. 27) quotes figures which indicate that typhus in previously vaccinated persons is milder and of shorter duration than in unvaccinated controls. BILBIN (p. 796) notes that in persons vaccinated against typhus the onset of the disease when it occurs is rapid, but its course is usually mild. Diagnosis may be difficult.

The information from which this series of summaries has been compiled is given in the abstracts which have appeared in the *Tropical Diseases Bulletin* 1945, v. 42. References to the abstracts are given under the names of the authors quoted and the page on which the abstracts are printed.

DURAND *et al* (p 107) tested the sera of a group of people in North Africa before and after inoculation of various vaccines by means of a protection test in which infective material was mixed with the serum and then injected into the skin of rabbits. Some of the sera gave protection before vaccination but many more after vaccination. Killed vaccines appeared to be more effective than live.

From experience of vaccinating mice FITZPATRICK (p 793) concludes that the toxic factor in epidemic and murine strains of rickettsiae is identical.

LEVKOVICH and PETRISHCHEVA (p 268) find no difference in effectiveness between vaccine of the Cox type mouse lung vaccine and vaccine prepared from lice except that one prepared from the whole bodies of lice may cause allergic skin reactions. They give details of their methods of dealing with the lice.

DOBOVICK and WYCKOFF (p 792) show that by the end of 1942 certain improvements had been made in the preparation of typhus vaccines which rendered them more effective and that the titre of the complement fixation reaction in guinea-pigs is a reliable indication of vaccine potency. They (p 882) give information on the techniques employed in preparing these vaccines.

In a discussion at the Royal Society of Medicine (p 979) STUART HARRIS remarked that all typhus vaccine used in the British Army since 1943 was of the Craigie type and FULTON made the point that when vaccines were standardized by counting the rickettsiae it was found that animal-lung and yolk sac vaccines gave similar degrees of protection. Fox knew of no authentic case in the Allied Forces of a person dying of typhus after having been properly vaccinated with the Cox-Craigie vaccine.

GALLARDO *et al* (p 23) describe their experiences in the preparation of typhus vaccine by the Cox method.

TOPPING and SHEAR (p 457) have shown that the supernatant fluid from a centrifuged suspension of epidemic typhus rickettsiae grown in yolk sacs contains a substance having the same immunological properties (complement-fixation and production of immunity in inoculated animals) as the rickettsiae themselves. This substance is probably soluble but may possibly be contained in very small rickettsiae. [See also GIROUD below.]

ROTH (p 719) reports reactions to typhus vaccine which are probably due to residual egg antigens.

Information on delousing and immunization against typhus is contained in the *Monthly Bulletin of the Ministry of Health* (p 879). This note was intended for the information of medical men in Britain.

HORRENBERGER and RENOUX (p 107) and SERGENT and HORRENBERGER (p 365) show that sheep and goats can be used in place of rabbits for the preparation of animal-lung typhus vaccine.

By adding sterile sulphathiazole to the suspensions of infected mouse lung used in making intranasal transfers RUIZ CASTAÑEDA and ROBERTO SILVO (p 193) have been able to check secondary infections due to Gram positive organisms and have made 74 successive transfers of two strains of *R. prowazeki*. This has proved to be of great value in the preparation of bivalent vaccine.

RUIZ CASTAÑEDA and SILVA (p 457) describe experimental work which indicates that animal-lung vaccine from animals infected intranasally by both epidemic and murine rickettsiae (bivalent vaccines) are more effective against subsequent infection with epidemic strains than vaccines of epidemic origin alone.

GIROUD (p 366) shows that rickettsiae may remain alive in infected animal lungs kept at -25°C for 14 months. There was no indication that the rickettsiae could undergo attenuation while preserving antigenic power.

GIBOUD (p. 368) has demonstrated experimentally that lung tissue in which there has been heavy growth of rickettsiae but from which the rickettsiae have been removed, possessed good antigenic properties and is effective as a vaccine.

VAISBERG *et al* (p. 549) show that the incidence of typhus in a group of medical employees who had been inoculated with a Russian mouse-lung vaccine was considerably lower than that in a comparable control group. A similar finding in other groups of people particularly exposed to infection is reported by RAVIACHICH *et al* (p. 549). When it occurred in the vaccinated, the disease was relatively mild. FAJERSTEIN (p. 456) has used a formalin vaccine from mouse lung preparations for vaccinating employees of the underground railway in Moscow. The protection afforded was moderately good.

OSBURN (p. 455) describes the preparation of an alum-precipitated vaccine from the peritoneal washings of South African gerbils infected with *R. prowazeki*. In spite of certain anomalous findings in the animal tests with this vaccine it appears to have some advantage over non-precipitated vaccines with which it was compared.

LEMAIRE (p. 268) states that the live vaccine of Blanc can be kept for an indefinite period when stocked in dry form *in vacuo*. It was used on a large scale during an epidemic of typhus in Algiers and the case incidence and fatality in the unvaccinated were 8 times and 5 times as high respectively as in the vaccinated.

CLAYTON and PÉREZ GALLARDO (p. 794) have used a "non-pathogenic and immunising strain of *R. prowazeki*" as a vaccine both in the living state and after desiccation. No serious reaction occurred in 2,217 persons vaccinated, except in one who had what might have been regarded as a mild attack of typhus. The Weil-Felix reaction becomes positive in almost half of those vaccinated. No estimate of the protective value of this vaccine is given.

BERGER and BRZEZINSKI (p. 966) have shown that the addition of petrol-ether extracts of liver or certain fatty acids to suspensions of rickettsiae has a pronounced antitoxic and antirickettsial effect.

BRAUN and UNAT (p. 108) have shown that intravenous injections of killed *Proteus O:19* provoke positive Weil-Felix reactions to the same organism, and argue that mixed vaccines of rickettsiae and *Proteus* administered intravenously may be more effective than rickettsial vaccines given subcutaneously.

Proteus O:19 type 1 vectors: louse and flea

Louse typhus

Epidemiology.—HUSSAIN (p. 881) notes that louse-infestation and typhus are common in the highlands of Kashmir and JACKSON (p. 891) also refers to typhus in this area.

SOFIA and SPADARO (p. 547) claim that both the murine and the classical type of typhus exist in Amara, Ethiopia.

Aetiology.—ELFORD and VAN DEN ENDE (p. 455) have studied the viability and filterability of typhus rickettsiae for details the original should be consulted.

ANDERSON (p. 106) has experimented on the survival of *R. prowazeki* in milk, water and other fluids.

COHEN and CHARGAFF (p. 192) have made highly technical studies of the composition of *R. prowazeki*.

A heat labile toxin separable from the rickettsiae of epidemic and murine typhus has been studied by KLINGLER and OLEVIA (p. 23).

GIBOUD and PANTHIER (pp. 104-985) have shown that the rickettsiae of louse-borne epidemic typhus may behave either as orchitic or non-orchitic strains according to the conditions in which they are transmitted by intra-peritoneal inoculation in guinea-pigs. They have now failed to infect rats by

intraperitoneal or lung inoculation of three epidemic strains maintained in rabbit lung passages and conclude that the rat is a sure test for the differentiation of epidemic and murine rickettsiae.

PSHEVICHNOV (p 269) infects lice by allowing them to feed through animal membrane on defibrinated human blood, to which an emulsion of infected louse intestine or guinea-pig brain has been added. The method of handling and rearing the lice is described by RAJKHER (p 270). SNYDER and WHEELER (p 987) have devised a technique for feeding lice on rabbits and for infecting them with typhus by this means. Infection of the lice occurred if they were fed shortly after the rabbit was inoculated, but if fed 117 hours after inoculation the results were negative. If proper precautions are taken lice may be used for the isolation of rickettsiae from patients [see LASKIN below].

Transmission—BLANC and BALTAZARD (p 715) demonstrated that human volunteers did not become infected when bitten by infected lice whose faeces were prevented from touching the skin. The natural reservoir of rickettsiae is infected louse faeces. GROMASHEVSKY *et al* (p 460) however contend that the only sources of infection in typhus are patients suffering from the clinical forms of the disease and the lice which have fed on them. If the spread of the disease has really been terminated it cannot again begin unless fresh cases are introduced into the community. [The authors do not support the view that inapparent cases occur and evidently do not think that infection occurs from the inhalation of dried infected, louse faeces which, in North Africa and elsewhere has been regarded as a likely source of renewed outbreaks (see PSHEVICHNOV this *Bulletin* 1944 v 41 836)].

TOKAREVICH (p 460) describes five laboratory infections with *R. prowazeki* two by droplet infection two by contamination of mucous membranes by infected louse faeces and one by inoculation. Two of the patients had been vaccinated and the author points out that this experience was in contradiction with the consistently negative results previously obtained when feeding infected lice on vaccinated persons. The reason is perhaps related to high dosage or to maturity of the rickettsiae in these accidental infections.

By injecting into animals material from the nose mouth and trachea of patients with typhus with negative results DRING (p 22) has shown that there is no direct evidence that transmission of infection from man to man can occur by droplets from the respiratory tract.

LINSKIS (p 988) reports a case of typhus contracted as a result of blood transfusion from a donor who was in the incubation period of the disease.

BLANC and WOODWARD (p 547) have shown that the monkey louse *Pediculus albidus* can become infected by epidemic typhus and that infection of ground up infected lice will transmit the disease. They have not proved that these lice can transmit typhus in natural conditions.

Pathology—RANDERATH (p 458) describes post mortem findings in typhus. Typhus nodules were never found in the heart which however showed a condition of typhus myocarditis. Circulatory failure was believed to be due to damage to the vasomotor centres and to be associated with the condition of the peripheral vessels rather than with myocarditis [see also the findings in scrub typhus below]. The most striking complication was diffuse haemorrhagic glomerulo-nephritis.

DURAN (p 459) describes the Fraenkel nodules of typhus. He regards the fundamental lesion of typhus as an endothelial necrosis of varying intensity of which should be sought in the original abstract.

AVTSYV (p 266) describes the pathological changes in the lungs of mice inoculated intranasally with suspensions of typhus rickettsiae.

Tests—**LASNIK** (p. 795) claims that examination of the gut of lice collected from typhus patients affords a good method of early diagnosis before the Weil-Felix test is positive. Typhus rickettsiae are present and can easily be distinguished from non pathogenic rickettsiae.

DE LA CAMARA (p. 984) reports an outbreak of typhus in Spain but notes that the results of the Weil-Felix test were irregular. In comment **MEDAW** emphasizes the importance of standard strains of *Proteus* and standard technique in such tests.

FROMME and **GAARE** (p. 197) have tested the specificity of the Weil-Felix reaction by the examination of a large number of sera obtained for tests for syphilis. They conclude that if a titre of 1 in 200 is accepted as a minimum, non specific reactions occur in only 1.2 per cent. of apparently uninfected persons. They conclude that in persons vaccinated against typhus and in those who have been living in infected communities the reaction may be positive possibly as a result of inapparent attacks.

SCHROER (p. 545) maintains that if the reagents of the Weil-Felix test are incubated together for 2 hours and then kept for 22 hours at room temperature the results in typhus are more clear-cut and there is no tendency for false positive results to develop in other diseases. The contrary view however is expressed by **WINKLE** (p. 545). The latter author (p. 546) discusses three Russian patients from the Far East who gave reactions to *Proteus OXK* and one German soldier who gave the same reaction probably as a result of infection of a wound with a strain of *Proteus*.

NELSON and **CRICKSHANK** (p. 363) have been unable to confirm the findings of **GRATCH** that the sera of pregnant women agglutinate *Proteus OX19* constantly and at high titres. Similarly **HOARE** (p. 794) failed to confirm the findings of **Gratch**.

BRUMPT (p. 197) describes a slide test with a suspension of *Proteus OX19* stained with methylene blue and in which a drop of the patient's blood is used, which gives results comparable with those of the Weil-Felix reaction. The test is rapidly performed and if it is done on photographic paper a permanent record may be obtained and kept.

VARELA (p. 364) thinks that the fact that guinea-pigs infected with typhus do not give a positive Weil-Felix reaction is due to the presence of an antigen in their tissues which is related to the antigen in *Proteus*.

COHEN (p. 981) has studied the chemical alteration of bacterial surfaces with special reference to the agglutination of *Proteus OX19*—the paper should read in original.

VAN ROOYEN (p. 194) has performed the rickettsia-agglutination test in 323 cases of typhus in the Middle East. In Egypt Iraq and Iran the results indicated that the epidemic strain was most common in Palestine the murine. When the epidemic reaction was positive at higher titre than the murine the case was regarded as of epidemic louse-borne type and when the murine titre was higher as of murine type but information regarding the epidemiological conditions is seldom sufficient to justify an opinion as to which vector was concerned in a particular case. Moreover in nearly 40 instances there was only moderate difference between the titres. Some cases suggested tick-borne typhus and it is possible that this form exists there. Captured rats gave the murine reaction. The author prefers a classification by vector and would avoid the use of the words epidemic and endemic in relation to typhus. Another account of the same work has been written by **VAN ROOYEN et al.** (p. 284).

RUZ CASTAÑEDA (p. 716) has used the rickettsia agglutination slide test in differentiation between epidemic and murine typhus with success in that agglutination of the homologous organism occurs at higher titre than that of the heterologous organism. Nevertheless cross agglutination does occur

especially with anti murine serum and epidemic rickettsiae which indicates that murine rickettsiae contain more of the epidemic antigen than *vice versa*. This may explain the greater cross protection from murine than from epidemic vaccines.

BRIGHAM and BENGTSON (p 552) show that the complement fixation test is a much more sensitive test of the occurrence of typhus in rats than the Weil Felix reaction. They support this conclusion by a large body of evidence.

WERTMAN (p 635) makes the point that when relatively crude egg yolk cultures of rickettsiae are used as antigens for complement fixation tests a non specific antigen from the yolk is present and may give false positive reactions especially with Wassermann positive sera and still more with the particularly sensitive technique of incubation for 18 hours at 4-8°C. This antigen can be removed by repeated washing and centrifugation.

DAMON and JOHNSON (p 990) prefer to carry out the complement fixation test at ice box temperature overnight rather than at 37°C for one hour.

SILVA-GOYTIA (p 718) has used the complement fixation test in Mexico and concludes that the typhus there is very largely of epidemic type but that there are some cases of murine origin.

SMORODINTSEV and DROBYSHEVSKAYA (p 196) have devised a complement-fixation test for typhus designed to detect in the patient's serum an antigen which is present in the early days of the disease but which is gradually neutralized by antibodies developed by the patient so that by the 10th day it cannot be detected. Inactivated serum from the patient is mixed with inactivated convalescent serum (which presumably contains the antibody) and with titrated complement. This mixture is kept at 0-2°C for 18 hours and the sensitized red cells are then added and incubated at 37°C. Hyperimmune rabbit serum would probably give more satisfactory results than convalescent human serum. SMORODINTSEV and FRADKINA [this *Bulletin* 1944 v 41 1021] had previously described a rapid slide-agglutination test for the detection of this antigen if these two tests are confirmed their value in diagnosis in the early stages of the disease are sufficiently obvious.

LEÓN (p 984) notes that the complement fixation test with an antigen prepared from *Proteus O\19* is more sensitive than the Weil Felix reaction.

GIROUD (p 199) uses a skin sensitivity test for typhus in which an animal-lung antigen is employed. A positive result is obtained after an attack of the disease or after successful vaccination and indicates a state of immunity. A negative result is an indication for vaccination it may occur in debilitated persons even after an attack of the disease. BISCHOFF (p 198) describes an intradermal test carried out with weak Weigl vaccine. A negative result is given in unvaccinated patients with typhus during the course of the disease and for 15 days afterwards and is taken to indicate the presence of specific neutralizing antibodies.

Clinical features—Clinical features of cases of louse-borne typhus are described by SINGH (p 24). The outbreak occurred in the Persia Iraq Field Force in 1943. ALCANTARA (p 988) describes the clinical features of typhus pointing out that the mildness of the disease in children which often causes it to be missed, is important epidemiologically. WU and LI (p 795) note the relative mildness of typhus probably louse-borne in South China.

WOODWARD and BLAND (p 199) have studied the cardiovascular system in typhus. They conclude that the abnormalities are due chiefly to the foci of necrosis in the smaller vessels and that there is little evidence of cardiac weakness. Renal damage is rare and the oliguria (in spite of large fluid intake) can be corrected by giving chlorides and overcoming dehydration. In treatment careful nursing and adequate fluid and supporting foods are needed. cardiac stimulants were not indicated in any case in this series. SIEDEK *et al*

(p 105) found evidence of cardio-vascular disorders in 45 per cent. of 500 patients with typhus but these are apparently associated with damage to the vasomotor nerve centres and the peripheral vessels lesions of the heart playing only a secondary part. CRIMIKO (p 106) however has found electrocardiographic evidence of myocardial lesions.

ASCHENBRENNER (p. 104) notes that the chief cause of death in a series of cases of typhus was damage to the central nervous system. Severe myocarditis was rare. He used strophanthin in large doses during the febrile period, and in smaller doses in convalescence when evidence of circulatory disturbance persisted.

V STOCKERT (p. 459) describes certain syndromes which result from localization of typhus lesions in various parts of the central nervous system—the mid brain bulbar and extrapyramidal syndromes. In the first the most important disturbance of the vegetative nerve centres is the characteristic fall of blood pressure but it is not certain how far myocarditis is responsible for this. SCHELLER (p 200) has contributed a discursive paper on signs and symptoms associated with the nervous system in typhus. KOVÁCS and V KUP (p. 461) describe the clinical features of typhus and outline a treatment which they believe to have reduced the severity of nervous symptoms and the incidence of complications.

MULLER (p 548) describes the ophthalmological changes in typhus which include the presence of typhus nodules in the retina or choroid, and retinal haemorrhages.

ASCHENBRENNER (p 25) remarks on the very great increase in blood urea which may be a feature of typhus. He is unable to explain it except as due to increased production of urea and diminished excretion owing to renal damage either inflammatory or functional.

WILCKENS (p. 266) describes the symptoms of typhus noting that an after fever lasting 1-2 days is relatively common. In treatment he found that administration of luminal was of some benefit. ASCHENBRENNER & MARX (p 105) note that an unexplained rise of temperature may occur during convalescence from typhus. They also give a list of the common complications of the disease.

RAETIG (p. 25) describes two cases in which, he claims, true relapse occurred after attacks of typhus. In comment MEGAN throws doubt on the diagnosis of the first febrile attack in each case. It is noted that each of these patients was treated by injection of convalescent serum and the question arises whether each was in fact infected by the serum.

Treatment—LEOMANS *et al* (p 201) report encouraging results in a small series of typhus patients treated with *p*-aminobenzoic acid in the first few days of the attack and compared with a series of comparable controls. The optimum dosage is not known but the initial dose was 4-8 gm. followed by 2 gm. every 2 hours until the temperature was normal. The drug was given suspended in 5 per cent sodium bicarbonate solution. The effect of this treatment was to shorten the febrile period and to reduce the severity of the disease. Some of the treated patients had a secondary rise of temperature soon after the end of drug treatment this was not serious. The effect of *p*-aminobenzoic acid, both in inhibiting the growth of rickettsiae in yolk-sac culture and in treatment of mice infected with a murine strain, was demonstrated by GREIFF *et al* (p 362). PRINCEBROOK (p 878) also discusses the therapeutic action of *p*-aminobenzoic acid in typhus. HAMILTON *et al* (p 786) describe the inhibitory action of *p*-aminobenzoic acid on rickettsiae (epidemic and murine strains) growing in yolk sacs of fowl embryos.

LEÓX (p 202) has used hyperimmune rabbit serum for the treatment of typhus giving 20 cc. intravenously at intervals of 12 hours until the temperature subsides. The results were apparently satisfactory in a small series of

cases. A beneficial effect of the use of hyperimmune rabbit serum in louse typhus is also indicated by the results obtained by STEVENS (p 384) in a small series of patients. SHUBLADZE *et al* (p 461) have immunized horses with infected mouse-lung preparations of *R. prowazeki* and have used the horse sera for treatment of typhus in animals with some success. Preliminary clinical trials in man have been promising.

Certain substances which are described in the original abstract were tested for activity against the rickettsiae of murine and epidemic typhus by ANDREWES *et al* (p 20). Activity was recognized in some of these drugs but they proved disappointing in the treatment of human typhus. SKORIN and KORSHUNOVA (p 638) have tested 56 compounds for chemotherapeutic activity in experimental typhus. In a critical evaluation of the many drugs which have been advocated by German medical men BRANDENBURGER (p 28) adopts an attitude of scepticism. He relies on careful nursing and the administration of plenty of fluid, with generous and varied diet.

Treatment by daily warm baths, injections of artificial blood and saline is advocated by LAMPERT (p 365) but the evidence of its value is not clear.

YARYGIN and NAGIBINA (p 989) describe the method of buxation which consists of alternately withdrawing and reinjecting 10 cc. of cerebrospinal fluid after the patient has been given large doses of sodium salicylate. This treatment (for details of which the original abstract should be consulted) was tried in typhus with some favourable results.

ALISOV and KOSSOVAJA (p 989) have observed some benefit from vaccine therapy in severe attacks of typhus.

LAURE (p 267) describes the types of gangrene seen in typhus and the treatment advocated, which consists of infiltration of the lumbar sympathetic ganglion with novocaine without adrenaline.

Control—SERGENT and BÉGUET (p 270) have used the insecticide powders MYL and DDT for delousing certain communities in Algeria. These preparations were very effective but the authors are pessimistic on the question of complete and permanent eradication of lice and conclude that these dusts can best be used by mobile disinfecting units when outbreaks of typhus occur.

BEACH and RENNIE (p 880) report four cases of typhus in prisoners of war returned to England from Germany. They had been dusted with DDT and were free from lice. MEGAW in comment makes the point that delousing by DDT does not sterilize infected louse faeces.

Louse and flea typhus

LEON (p 193) argues that typhus is caused by a single species of rickettsia of which there are two strains [? varieties] *R. prowazeki prowazeki* and *R. prowazeki mooseri*. The former does not provoke vaginitis in animals; the latter does so. Either strain can cause endemic or epidemic typhus and either can be of high or low virulence. The author supports his conclusion by records of his own work. In comment MEGAW points out that although these organisms cannot be clearly differentiated by their capacity to provoke orchitis they can be distinguished by complement fixation and rickettsia-agglutination tests. From the point of view of control, the vector louse or flea is important.

SILVA and RUIZ CASTAÑEDA (p 990) having infected guinea-pigs with both epidemic and murine rickettsiae simultaneously have found that transfers through male guinea-pigs favour the isolation of the murine strains and through females of the epidemic strains.

ANDERSON (p 192) has shown that the cotton rat *Sigmodon hispidus hispidus* is as highly susceptible as the South African gerbil to infection with classical

and murine strains of typhus rickettsiae it has therefore been used in laboratory research work. Sera of infected cotton rats do not agglutinate *Proteus* OX19.

Flea typhus

SOFIA (p. 109) has isolated rickettsiae of the murine type from man in Asmara (Eritrea) and also from the brains of wild rats. HARRINGTON and YOUNG (p. 271) have isolated murine strains of rickettsiae from rats and from a patient in South Africa, near Port Elizabeth.

POLLARD and AUGUSTSON (p. 551) perform complement fixation tests on rats to detect evidence of murine typhus in them. They have obtained positive results in endemic areas but not where the disease is not known to occur. Some of the rats giving positive tests were captured in theatres—this fact may explain certain outbreaks in man.

IRONS *et al.* (p. 462) have isolated murine rickettsiae from *Ctenocephalides felis* from kittens probably connected with a human outbreak. It is possible but unlikely that the fleas acquired the infection from rats and the present finding indicates that cats may be a reservoir of infection in certain circumstances.

According to evidence collected by RUIZ SÁNCHEZ (p. 272) the endemic typhus of Guadalajara, Mexico is of murine origin. VARGAS (p. 706) has isolated a strain of murine rickettsiae from a patient in El Salvador. MACCHIAVELLO (p. 103) has studied strains of rickettsiae isolated from patients or from lice in Ecuador. One of these was regarded as a murine strain but the other two behaved irregularly in animals. The author does not think that the terms orchitic and murine as applied to strains of rickettsiae are synonymous. MONTORYA (p. 551) reports an outbreak of typhus which he thinks was murine in origin in Colombia.

ALICATA and BREAKS (p. 271) have isolated rickettsiae from a patient in Honolulu which were identical with a standard murine strain, and from a high proportion of rats in the area. Cats, dogs and the fleas collected from them were negative.

LIU (p. 719) has isolated rickettsiae of murine type from rats, rat fleas and lice during an outbreak in Perang. He thinks the human disease may have been louse-borne but MEGAW, commenting on this, is not convinced that louse-transmission was conclusively proved.

JETTMAR and SHIGAX (p. 981) report on the Weil-Felix reaction in man and rats in Kweichow, China.

BLANC *et al.* (p. 713) have shown that the ass-louse *Haematopinus asini* may transmit murine rickettsiae and *Yenopsylla cheopis* and *Pulex irritans* epidemic rickettsiae. The fleas *X. cheopis* and *Ctenocephalides canis* do not appear to be able to transmit the rickettsiae of Rocky Mountain and boutonneuse fevers.

DAMON and JOHNSON (p. 637) compared freshly prepared rickettsial suspensions (epidemic or murine types) with commercial vaccines in relation to their usefulness in the complement fixation test for typhus of murine type. The best results were obtained with the fresh suspension of the murine type.

ARBOVA (p. 990) quotes evidence which suggests some slight favourable effect in the treatment of flea borne typhus with mepracme.

Proteus OXA type I vector mice

MEGAW (p. 797) has contributed a comprehensive account of scrub typhus, in which he shows that during the war there has been an average case-mortality rate of 10–15 per cent, a high incapacitation rate and a depressing psychological effect. He discusses classification, epidemiology and transmission and in relation to the clinical findings makes the point that a necrotic ulcer is not

always present. No adequate summary of this paper and of the comments of LEWTHWAITE who reviewed it is possible in brief space and the original should be consulted. It was a timely account of an important disease.

FARNER and KATSAMPES (p 272) have compiled a summary of available information on tsutsugamushi disease which should be read in the original.

DE VIDAS (p 882) describes the clinical and pathological features of scrub typhus as he saw it in New Guinea noting that the maximum titre of the Weil-Felix reaction with *Proteus* OXA occurred 22-25 days after onset. SATHI and SILBERSTEIN (p. 885) also report on cases from New Guinea.

SINGH (p 883) gives an account of an outbreak of scrub typhus in Burma in soldiers who had camped in a rural area. MENON and IBBOTSON (p 884) record an outbreak in a unit which entered a typhus island in N.E. Burma. Clinical features and complications are described, and treatment is outlined. The authors note that malaria was so common that a therapeutic course of mepacrine was given at the onset in all cases.

HAY (p 109) describes an outbreak of scrub typhus in a force of Royal Marines who landed on an unnamed coast in the Far East. These men had been working in close contact with scrub conditions. The symptoms are described, but the description should be sought in the original abstract. Primary lesions once thought universal in this disease were rare. Diagnosis was confirmed by agglutination of *Proteus* OXA in high titre in all cases. It was found that local inhabitants also gave positive reactions with *Proteus* OXA and it seems probable that all local children become infected at some time and that local adults possess some degree of immunity. Larval mites probably *T. deliensis* were found on trees and grasses and on rats chiefly *Rattus rattus frugivorus*. Serological tests on rats indicated that the disease was present in them. Later evidence (MANSON *J. Roy. Soc. Med. Ser.* 1946 v 32 105) makes it clear that this outbreak also referred to by ZAIR (below) occurred in the Maldive Islands.

WILLIAMS (p 367) has published a list of mite vectors and animal reservoirs of tsutsugamushi disease. [The evidence available for some of the mites mentioned is somewhat tenuous. The mites definitely incriminated in the literature appear to be —

Trombicula akamushi

Trombicula deliensis

Trombicula fletcheri (probably = *T. akamushi*)

Trombicula walchi (probably = *T. deliensis*)

In addition *T. minor* (= *T. hirsti*) is suspected.]

BLAKE *et al.* (p 991) made a very thorough study of tsutsugamushi disease in New Guinea. They point out that the only mite hitherto proved by experiment to be a vector is *T. akamushi* though there is much evidence to incriminate *T. deliensis*. The only animals so far found infected in nature are the vole *Microtus montebellii* and undetermined species of wild rats in Malaya. They isolated strains from *Trombicula fletcheri* (= *akamushi*) which were identical with those isolated from man. The Syrian hamster was found to be specially suitable for passage. The authors give descriptions of the disease in man. This long monograph should be read in original. KOHLS *et al.* (p 993) report a continuation of the same work in which they recovered *R. orientalis* from pools of *T. fletcheri* (= *akamushi*) and *T. walchi* (= *deliensis*). These were taken from *Rattus concolor browni*. The rickettsiae have also been recovered from this rat.

McCULLOCH (p 369) makes the point that all the species of mites which occur in countries in which scrub typhus is endemic should be regarded as potential vectors of that disease. [Such a view needs verification.] He describes their

habits and the means of controlling them. WOMERSLEY and HEADLIP (p. 28) have written a comprehensive paper on the Trombiculinae of the Austro-Malayan and Oriental Regions. No further abstract of this is possible.

From his experience of three outbreaks of scrub typhus COOK argues that the possibility should be entertained that this disease may be transmitted by ticks (as has previously been suggested by workers in the Netherlands East Indies).

In Ceylon, LUCAS (p. 886) has isolated a strain of *R. tsutsugamushi* [*R. orientalis*] from man by passage through guinea-pigs, white rats and white mice. He considers the white mouse to be the animal of choice for this work. VAN ROOYEN and DAKSKIN (p. 463) note that two species of Egyptian gerbils and the jerboa are extremely susceptible to the rickettsia of scrub typhus.

SYVERTON and THOMAS (p. 879) describe a method of staining *Rickettsia tsutsugamushi*.

HICKS (p. 554) describes the post mortem findings in scrub typhus. The chief histological changes were proliferation of the reticulo-endothelial tissues and infiltration of interstitial tissues with mononuclear cells, especially in the heart, lungs and spleen. The naked-eye changes are described.

WILLIAMS *et al.* (p. 369) give a detailed account of the clinical features of scrub typhus drawn from an experience of 626 cases. The original abstract should be consulted for details, but it may be mentioned that the value of the Weil-Felix reaction with *Proteus OXK* was confirmed, provided the strain of *Proteus* is suitable—that an eschar was seen in only 59 per cent. of the cases, that the death rate was profoundly influenced by lowered resistance due to hardship, malaria and dysentery, and that there was no evidence of permanent cardiac disability in those who recovered.

LIPMAN *et al.* (p. 371) also describe the clinical features of scrub typhus, and the original abstract of this paper also should be consulted for details. They give a list of complications in which cardiovascular disturbances are prominent. A similar description is given by BERRY *et al.* (p. 535) who regard the vascular changes found at post mortem to be of primary importance, myocardial and pulmonary lesions being secondary to them. They note that obstinate cardiac neurosis may occur if any suggestion of heart disease is made to the patient. LEVINE (p. 556) also stresses the fact that suggestion of heart disease may make an almost ineradicable impression on the minds of people suffering from scrub typhus leading to neuro-circulatory asthenia. In actual fact there were only two cases of true cardiac disease in 130 patients.

A comprehensive description of the clinical features of scrub typhus is given by MACHELLA and FORRESTER (p. 804).

In *Army Medical Department Bulletin* No. 41 (p. 112) there is a note on fluid retention in scrub typhus. This is a common feature of the disease and is often relieved by diuresis which occurs relatively suddenly about the 14th day of disease; this is associated with subjective improvement and is usually followed by reduction of the fever.

A study of the blood chemistry in scrub typhus is reported by GOTTFRIED (p. 885); the details are numerous and should be sought in the original abstract.

WEDD (p. 111) reports an increase in speckled lymphocytes in the convalescent stages of scrub typhus which is seen only rarely in other diseases. The cells are described, and it is noted that speckling occurs in a proportion of lymphocytes in normal blood.

LOCUR (p. 274) describes an outbreak of mite typhus among American troops on an island in the S.W. Pacific and outlines the preventive measures which, when adopted, were successful. These comprised preparation and treatment of camping sites, rat control, the use of dimethyl phthalate and insecticidal powder. [In the abstract the word *kunal* is a misprint for *kunai* grass.]

In an outbreak of scrub typhus in the south Pacific the incidence declined sharply after certain control measures were instituted —trapping of rats cutting and burning of *Kunai* grass spreading of sand wearing of leggings and the liberal use of repellents (MOREHEAD p 720) In the *Journal of the American Medical Association* (p. 799) is a note to the effect that the United States forces have substituted benzyl benzoate for dimethyl phthalate for the impregnation of clothing as a protection against mites.

In the prevention of scrub typhus among men engaged in clearing scrub ZAIR (p. 111) notes that bulldozers are useful for this purpose and that if manual clearing is necessary the scrub should first be sprayed with kerosene and burned. Advice is given in regard to rat-control operations.

LEWTHWAITE (p 980) refers to the immunity conferred by an attack of tsutsugamushi disease

STEPHENSON (p 553) reports a single case of fever of the typhus group with a strong reaction to *Proteus OXA* in the Sudan where mite-borne typhus is not known

Indeterminate type Vector tick

MARIOTTE *et al* (p 721) report natural infection of *Rhipicephalus sanguineus* with rickettsiae of Rocky Mountain fever in Mexico BUSTAMANTE and VARELA (p 203) have found Rocky Mountain spotted fever in rural areas of Mexico The vector was probably *Rhipicephalus sanguineus*

PLOTZ *et al* (p 636) have tested the sera of persons with Rocky Mountain spotted fever by the Weil-Felix complement fixation rickettsia agglutination and mouse neutralizing tests to find a satisfactory means of differentiating this disease from epidemic and murine typhus The Weil-Felix results were irregular as is usual in tick borne typhus and the rickettsia agglutination test did not afford good differentiation The complement fixation reaction gave uniformly consistent results with clear-cut differentiation It was found that antibodies capable of neutralizing epidemic and murine toxins were present in Rocky Mountain spotted fever [See also WOLSTENHOLME and GEAR above.]

HARRELL *et al* (p 373) challenge statements which have been made to the effect that intravenous medication does more harm than good in Rocky Mountain spotted fever and they claim that the collapse of the peripheral circulation which occurs corresponds to the condition of shock and may need treatment with plasma or blood. The administration of fluid should be very carefully controlled as to amount and type—saline and glucose or blood. The same authors (p 888) think that in Rocky Mountain fever as in burn shock there is extensive leakage of proteins through the walls of blood vessels into the tissues. They treat their patients therefore with transfusions of plasma one effect of which is to promote the reabsorption of crystalloids into the vessels This treatment is carefully controlled by estimation of non protein nitrogen, serum proteins and chlorides of the blood A high-protein diet is useful.

The action of *p*-aminobenzoic acid in guinea-pigs infected with Rocky Mountain fever appears to be purely suppressive but it prevented death in many of the animals though all controls died (ANIGSTEIN and BADER p 888)

EDMONDS (p 464) has treated one patient suffering from Rocky Mountain spotted fever with penicillin. This was apparently very successful but no value was found by FITZPATRICK (p. 996) in the treatment of experimental Rocky Mountain spotted fever with penicillin.

HEILIG and NAIDU (p. 30) refer to the fevers of the typhus group which have been seen in the State and City of Mysore and to the complement-fixation tests carried out on some of these cases by TOPPING The results of these tests

indicate that the disease is related to Rocky Mountain spotted fever rather than to other members of the typhus group. Cases of some fever of the typhus group but without rash, are described from the United Provinces of India by BARDHAN (p. 29). PRADHAN (p. 29) describes cases of a typhus-like disease, possibly transmitted by ticks which he has seen in recent years in Berar, India.

PESTANA (p. 638) gives reasons for his view that the typhus of São Paulo may not entirely be of the Rocky Mountain type but may include cases of the flea borne murine type.

PATISCO-CAMARGO *et al.* (p. 799) proved that an adult *Ornithodoros parkeri* contained living rickettsiae 1 087 days after a feed on a guinea-pig with the spotted fever of Tobia. A related species *O. rufus* is a potential vector and is abundant in Tobia.

DE MAGALHÃES and ROCKA (p. 986) have produced inapparent infection in certain common Brazilian small animals by injection of infective material from Brazilian exanthematic typhus. They describe the clinical types of this disease. [This form of typhus is presumably tick borne.] The same authors (p. 988) have tried penicillin in Brazilian typhus [tick borne] there seems to be some slight beneficial effect.

RODHAIN and BARLOVATZ (p. 887) discuss the histology of the eschar in the disease found in the Belgian Congo which resembles boutonneuse fever. An outbreak of tick typhus in East Africa is described by WALKER (p. 720) in which a local lesion was found in every case.

CAVAZZI (p. 113) has seen five cases of boutonneuse fever in the Ethiopian highlands.

KORSHUNOVA *et al.* (p. 274) give an account of tick typhus as it occurs in central Siberia. The infection is apparently found in ground squirrels and other rodents and is transmitted to man by *Dermacentor nitidus* and possibly by other ticks. A strain isolated from man immunized animals against Marseilles (? boutonneuse) fever. SHKORBATOV (p. 484) discusses tick-borne typhus in the far east of the Soviet Union where the vector appears to be *Dermacentor sibiricus*. Serum reactions are most commonly given to *Proteus* O:19.

Bullis fever

BADER and ANIGSTEIN (p. 639) report their experiments to determine the specificity of the rickettsiae isolated from *Amblyomma americanum* and from a patient with Bullis fever. The strains are not related to Q fever or Rocky Mountain spotted fever. The details of the experiments should be sought in the original abstract but in comment MEGAW remarks that perhaps more than one short tick-borne fever may have been included under the name Bullis fever. BLAIR and BADER (p. 709) have induced fever in nine volunteers inoculated with material derived either from patients with Bullis fever or from infected ticks and subsequently passaged through guinea-pigs. Many other attempts to infect man were unsuccessful. LIVERAY and POLLARD (p. 203) have carried out complement fixation tests on patients recovered from Bullis fever using an antigen prepared from the spleens of infected mice. Most of the tests were positive. Control tests were negative. Sera from certain animals shot in the neighbourhood were also positive.

BRENNAN (p. 799) gives a list of ticks and vertebrates at Camp Bullis. Some of these may perhaps be important in relation to Bullis fever.

Trench fever

In a discussion of trench fever v. BORMANN (p. 462) states that abortive attacks are common that shin-bone pains have little diagnostic value and that less than one-third of the attacks in one outbreak were of the periodic

type A pronounced leucocytosis with relative lymphocytosis is a feature of the febrile periods of trench fever with a return towards normal during the afebrile intervals (BIELER p 204) HELD (p 113) describes nodules resembling rheumatic nodules in the scalp and the skin of other parts of the body which he believes to be the physical basis of the headaches shin-bone pains etc of trench fever

REUTER (p 204) describes trench fever

KIBLER (p 639) notes that there may be difficulty in differentiating trench fever from influenza, paratyphoid typhus and wound sepsis The clinical features are very variable He points out that the blood may be infective for a long time and that it is therefore unsafe to use the patient as a blood donor for two years after the attack

REUTER and SCHÄFER (p 204) think that war nephritis and trench fever are variants of the same disease largely because the periodicity and the pains are of the same type and because nephritis often occurs in trench fever

Solustibosan has been found useful in the treatment of trench fever (EBERLIN p 31) BEIGLÖCK and LOSCHER (p 31) have treated trench fever with Pyrifur a colon bacillus vaccine with some benefit Charles H Wilcocks

MALARIA

MACARTHUR, W. A Brief Story of English Malaria. *Post-Graduate Med J* 1946 July, 22, No 249 193-200

SEZONISMO Lisbon. Dez anos de luta contra a endemia [Ten Years of Antimalarial Work in Portugal.] 159 pp. (Publicação da Direcção de Serviços Anti Sezonáticos 1942.)

— A luta contra a endemia no ano de 1941 [Antimalarial Work in 1941] 176 pp (1942.)

— A luta contra a endemia no ano de 1942. [Antimalarial Work in 1942.] 230 pp (1943)

— Trabalhos originais-1942. [Original Papers, 1942.] 212 pp (1943)

— Trabalhos originais 1943 [Original Papers, 1943] 90 pp (1944)

This publication is issued each year by the Ministry of the Interior Public Health Department Lisbon, and is a record of the antimalarial activities of the previous year The word Sezonismo was used for malaria by Ricardo JORGE who though not the originator of the Portuguese antimalaria organization was well known for his work on the subject.

The first number of *Sezonismo* issued in 1942, contains an account of 10 years of this work up to 1940 The later numbers cover the years 1941 1942 and 1943 separately Those who wish to follow the malaria investigations in Portugal should consult these publications

In addition to this general account of routine work, a separate publication with the same name is issued each year and contains original papers of work done in the previous year

RIBBANDS C. R. *Effects of Bush Clearance on Flighting of West African Anophelines.* *Bull. Entom. Res.* 1946 May v. 37 Pt. 1 33-41 2 figs.

The experiments described in this paper were conducted in an attempt to discover if the eradication of low vegetation around human dwellings reduced the numbers of anopheline mosquitoes attracted to them.

The main work was done at a village near Sekondi, Gold Coast between January and March 1942. In this village all but three of the huts were pulled down—the observer used one of them and seven Africans were installed in the other two. There was a large swamp 880 yards to the east. To allow for any differences in individual attraction to mosquitoes the Africans were regularly changed about. Daily catches of mosquitoes were made in the two huts between 7 a.m. and 9 a.m. and night catches were made in one of them. These, the experimental catches, were compared with simultaneous control catches "made in three other huts—one the "inner control" hut 190 yards away was newly erected for the experiment in the direction of the swamp and was occupied by three Africans. The other two the outer control huts were already established in a south easterly direction—one at 650 yards distance occupied by three Africans and one at 880 yards occupied by one African—the catches in these two huts were averaged. After three weeks the bush was cleared around the two experimental huts for an average radius of 140 yards; this work took five days. Catching continued during this time and for another three weeks.

Counts of anopheline mosquitoes caught in the experimental huts were calculated as percentages of the corresponding counts in the control huts. These figures are presented graphically and in tables in three groups—before, during, and after the bush clearance. They show little difference between the proportion of female *A. funestus* and *A. gambiae* caught in the experimental huts after the clearance, and the proportion which reached the huts before the clearance—males entered in the same proportion as before. During the clearing operations the proportion of females dropped to nearly a quarter and of the males to one-half of that before the clearance—this reduction is attributed to the masking of the scent of man by the odour of the cut decaying vegetation.

A somewhat similar experiment had already been made during August and September 1941 at Aberdeen near Freetown Sierra Leone, where the predominant anopheline was *A. melas*. Catches were made for 14 nights in seven huts—six of them in a clearing and the seventh 25 yards from the others but ten yards inside the bush which reached 15 ft. in height—the African occupants

changed huts in rotation. Catches made in the bush hut were compared with those made in the nearest hut in the clearing and though there were variations on different nights the bush hut provided an average nightly yield for the 14-day period of 47.4 per cent. of the total catch.

There are features about these experiments which may appear to be unsatisfactory to the reader such as the number of Africans, number size and age of huts but the author believes that the results indicate that bush clearing around dwelling places is not justified as a measure for reducing anopheline infestation—a conclusion which is meant to apply only to *A. gambiae* and *A. fimestilis* in West Africa.

VARGAS L. Consideraciones sobre el complejo del *Anopheles pseudopunctipennis* [Studies on the *A. pseudopunctipennis* Complex.] *Rev Inst Salubridad y Enfermedades Trop Mexico* 1945 Dec. v 6 No. 4 265-70 1 fig. [15 refs.] English summary

The *Anopheles pseudopunctipennis* complex studied up to now discloses the following subspecies: *typicus* Theobald 1901, *franciscanus* McCracken 1904, *bovdi* Vargas 1939 and *willardi* Vargas 1941. The author mentions the most remarkable morphological data useful in the identification of these. The subspecies *typicus* acquires importance in the transmission of malaria only when the high numbers of individuals form a large population.

ANY TROP MED & PARASIT 1946 Apr v 40 No 1 80-87 7 figs on 2 pls. The Effects of Mepacrine on the Gastro-Intestinal Tract of Man. [Army Malaria Research Unit Oxford (MAGRAITH B. G. *et al*) & Nuffield Institute for Medical Research, Oxford (FRANKLIN K. J. *et al*)]

Mepacrine was given to numerous volunteers in various doses and one and a half hours later they were given a barium meal so that the movements of the alimentary canal could be observed radiologically. Twelve women received single doses of 0.6-1.0 gm. mepacrine. Clinically they experienced headache, often severe, nausea, sometimes repeated vomiting, colicky abdominal pain and diarrhoea. In more severe cases, fever and prostration occurred. These symptoms began to disappear after 8-9 hours. Radiologically immediately

after the taking of the barium meal there was gastric hypersecretion, hyperperistalsis increase of tone of the pyloric antrum followed by atony and pylorospasm. Emptying of the stomach was delayed. The intestines were abnormally active and the rate of passage of the meal along them was increased, although there was delay at the ileo-caecal valve. Once the meal entered the colon it advanced very rapidly there was also marked outpouring of secretion in the colon. The gall bladder appeared normal, and no significant change could be detected in the flora of the faeces.

On the other hand a large number of volunteers on a suppressive régime of 0.1 gm. mepacrine daily, rarely showed gastro-intestinal disturbances, and such disturbances as did occur were slight or unimportant. Fractional gastric analyses were carried out on the second day of taking 0.1 gm. mepacrine but they revealed no significant abnormality. In 12 volunteers gastroscopy was performed. The gastric mucosa as a whole was normal, but immediately around the site of the tablet there was hyperaemia, and the accumulation of thick mucus but this effect was too slight to explain the symptoms which are sometimes experienced. Two patients with quiescent chronic ulcerative colitis received 0.1 gm. mepacrine daily for a fortnight there was no change in their general condition or in the bacterial flora of the stools.

It is recalled that widespread disturbances especially vomiting and diarrhoea, occurred among the troops in North Africa in 1943 when they were given 0.2 gm. mepacrine twice weekly. The symptoms occurred most frequently after the third dose developing 3-10 hours after the dose had been taken. Investigations at the time had shown that they were not psychogenic, they were not due to abnormally toxic batches of mepacrine and they were not due to some bacterial infection. In the present investigation eight volunteers were given 0.2 gm. twice weekly. Six volunteers showed no ill-effects two volunteers experienced severe symptoms after the third dose resembling those seen in North Africa. The concentration of mepacrine in the plasma of these two volunteers was within normal limits. It is concluded that when a dose of mepacrine is repeated at intervals greater than two days the tolerance for mepacrine in some of the subjects may be reduced by the time the third dose is given, and that such a régime should never be used. MAXDEROS, A. G. [D.D.T. (Neocid, Gesarol, Glx) A New Insecticide which will revolutionize the Methods of controlling various Diseases transmitted by Insects.] *Helleniatr Salonica* 1945 repr. 16 pp. [In Greek. English summary.] [Summary taken from *Rev. Applied Entom.* Ser. B 1946 June v. 34 Pt. 6 99.]

From laboratory and field experiments carried out in Greece in 1943 and 1944 it is concluded that Neocide (5 per cent. DDT in talc) is effective against larvae and adults but not eggs or pupae, of *Anopheles* and *Culex*. Contact with the powder or with a suspension of 1-6 gm. Neocide in 1,000 cc. water with the addition of 2 cc. kerosene caused adults and larvae to die in 3-4 hours. Ceilings and walls of bedrooms or stables can be kept free from mosquitos for at least five weeks by the application of 1 gm. Neocide in 2 cc. kerosene and 18 cc. water per sq. metre [4.65 mg. DDT per sq. ft.]. A suspension of 2 gm. Neocide and 2 cc. kerosene in 1,000 cc. water applied at 70 cc. (7 mg. DDT) per sq. metre [about 1 oz. DDT per acre] to breeding places of races of *Anopheles maculipennis* Mg. including var. *sacharovi* Fabr. (*clutus* Edw.) gives very good initial kill but an application must be made every week. In the fast flowing streams in which larvae of *A. superpictus* Graess. occur better results are obtained if a larger quantity of Neocide is used (160 cc. of a suspension containing 5 gm. Neocide and 10 cc. kerosene per 1,000 cc. water). In 1944

this dosage was used in breeding places in Salonica and the total number of Anophelines taken in ten catching stations in the city and its outskirts was 85 compared with an average of 69.1 and a range from year to year of 38.8 to 166.5 in 1939-43 when Paris green was applied by a dustless method. Comparative figures are given showing the amounts of DDT required per unit area for spraying walls or treating breeding places by the methods of application described by the author and by Smith.

TRYPANOSOMIASIS

STEWART J. L. Eradication of *Glossina* in the Naboggo Valley, Gold Coast. *Bull Entom. Res.* 1946 May v 37 Pt 1 99-103

Animal trypanosomiasis made it impossible to keep any cattle except the relatively resistant and inferior local dwarf breed in the Naboggo valley. The tsetse present consisted of *Glossina palpalis* and *G. tachinoides*. The fly appeared dependent on the bush fringing the river, a meandering stream which is converted into separate pools in the dry season (November to June). The fringing bush in this whole valley was cleared selectively. Experiment showed that only the trees fringing the water need be removed, these were cut at the beginning of the dry season and the stumps completely burned in May. This needed supervision but with care gave excellent results, maintenance of the clearing proved practicable.

Erosion after clearing was feared but the river never flows rapidly and the quick and profuse growth of grass in cleared areas held the soil together. Some damming was done to conserve water for domestic use and for irrigation as well as to prevent erosion.

The economic value of the work was soon manifest. The valley was able to maintain a much larger population of cattle of superior breeds (susceptible to trypanosomiasis).

Kenneth Mellanby

TRYPANOSOMIASIS COMMITTEE OF SOUTHERN RHODESIA. The Scientific Basis of the Control of *Glossina morsitans* by Game Destruction. *Rhod Agric J* v 42 No 2 124-8 also as *Bull Minist. Agric.* [S Rhodesia] No 1303 6 pp Salisbury S Rhodesia 1945 [Summary taken from *Rev Applied Entom.* Ser B 1946 June v 34 Pt 6 103-4]

Measures have been taken in Southern Rhodesia during the past 25 years to create and maintain game-free zones in order to prevent the extension and ultimately cause the retrogression of *Glossina morsitans* Westw. The regular hosts of *G. morsitans* are the larger grazing and browsing mammals available all the year round and it also has occasional hosts which are nocturnal, exceptionally active, migratory or seasonally hidden by long grass. It must obtain meals at regular intervals to replace water lost by evaporation. The extermination of most of its usual hosts deprives it of opportunities of obtaining regular meals and forces it to expend energy seeking other sources of food and thus lose much moisture so that the death rate rises far above normal and

females may abort. To eliminate *G. morsitans* from an area, therefore it is not necessary to exterminate every species of animal on which it can feed—it is sufficient to eliminate those that provide a dependable source of food throughout the year. When this has been done the fly cannot support life when grass is high and dense. As *G. pallidipes* Aust. can find its prey even in thick vegetation game destruction has to be very drastic to be successful by itself in eliminating this species. If a zone that has been freed of *G. morsitans* has its ends in fly-free country or is 50 miles or more long game can be allowed to re-enter it by moving the shooting zone forward into the fly belt without increasing its width (10–20 miles). The desirability of doing this is discussed. It is pointed out that the presence of much game in a cattle area results in loss of pasturage and increases the difficulty of controlling tick borne and other diseases of stock and that certain species destroy crops or are a menace to human life.

FLOCH H & DE LAJUDIE P. Recherches sur la trypanosomiasse humaine américaine en Guyane française. *Rhodnius prolixus* et *Rhodnius pictipes* vecteurs naturels de choix de *S. cruzi* [Study of Trypanosoma cruzi Infection in French Guiana.] *Institut Pasteur de la Guyane et du Territoire de l'Inini* Publication No 117 1945 Nov 5 pp

Triatomidae captured in French Guiana belong to one or other of the following species: *Rhodnius prolixus*, *R. pictipes*, *Triatoma rubrofasciata*, *Parstrongylus gemiculatus* and *Eratyrus mucronatus*. LAROUSSE has recorded *R. robustus* also but the authors have not met with it. They have found trypanosome infection in *T. rubrofasciata*, *R. prolixus* and *R. pictipes* but in the case of the first they could not obtain the blood forms and animal inoculations in the laboratory remained negative and on one occasion only was xenodiagnosis positive. They think therefore that the trypanosome present in this insect is more often than common in bats not the human type of *T. cruzi*. Of four specimens of *R. pictipes* three were infected this has not before been noted as infected in nature. Further examination has shown that of 72 *R. pictipes* examined 65 were positive of *R. prolixus* 68 out of 80 but only 29 out of 91 *T. rubrofasciata*. The two former are therefore to be regarded as the natural vectors in French Guiana, *T. rubrofasciata* less commonly. The authors conclude. The experimental xenodiagnostic test seems to us to be of much value in determining what are the natural vectors of choice of *S. cruzi* in any given district. H Harold Scott.

BRASIL, A. Forma cardíaca crônica da Doença de Chagas. [Chronic Cardiac Lesions in Chagas's Disease.] *Hospital* Rio de Janeiro. 1946 Feb., v 29 No 2, 199–224 23 figs. [17 refs.] English summary

In August 1941 a Congress lasting for a week was held in Belo Horizonte in honour of Carlos Chagas. This is one of the papers read at that Congress. It is a concise but comprehensive account of the cardiac complications of this disease, dealing with the symptoms, diagnosis, prognosis and treatment and illustrated by 89 electrocardiographic tracings. Diagnosis is stressed between

this and arterio-sclerosis syphilis rheumatic carditis diphtheria congenital heart disease among other conditions. The whole is a very readable summary but there is nothing fresh and it does not lend itself to abstract. Those wishing to renew their knowledge of the subject would do well to read the English summary which is fairly full and contains all the important points of the original.

RAMOS J Jr & LAUS F J A. Miocardite crônica na tripanosomíase americana. Considerações clínicas em torno de seis casos. [Chronic Myocarditis in American Trypanosomiasis. Discussion of Six Cases.] *Hospital Rio de Janeiro* 1946 Feb v 29 No. 2 231-50 14 figs English summary.

Evidence has been accumulating in recent years to show that sufferers from non valvular disease of the heart often owe their condition to *T. cruzi* infection. The present communication deals with six patients 5 men and 1 woman their ages ranging from 29 to 66 years. The dates of infection could not be determined in four in the other two it was 10 and 15 years previously but all had lived in *Triatoma*-infested localities. Their symptoms were mainly dyspnoea and epigastric pain on exertion and marked debility with palpitation and headache giddiness and cough with mucoid sputum. None of these symptoms is of course characteristic of Chagas's disease they are common to myocarditis of any origin but electrocardiograms show that the lesion is in this disease situated in the Bundle of His or in the sinoauricular node [we must remember that the conclusions are here based on a very small number of cases] with resultant arrhythmia and signs of heart-block. Of the six cases detailed three ended fatally with the usual signs of cardiac failure. The others improved in that oedema cleared up the dyspnoea became less troublesome and the heart diminished in size. These three were diagnosed, one by a positive xenodiagnostic test the other two by positive Guerreiro-Machado reactions. The three fatal cases had given negative results to xenodiagnosis but the Guerreiro-Machado test could not be carried out owing to temporary lack of antigen diagnosis in them was made by post-mortem findings. The moral to be drawn from this is that *T. cruzi* infection should be suspected and looked for in all patients with myocardial lesions who live in or have come from regions where the vectors prevail.

MAZZA, S BASSO G & BASSO R. Investigaciones sobre enfermedad de Chagas. Esquizontripánides ulcerosas tardías en enfermedad de Chagas y otras manifestaciones eruptivas. [Studies in Chagas's Disease Late Ulceration and other Outaneous Manifestations.] *Universidad Buenos Aires Misión de Estudios de Patología Regional Argentina (Jujuy)* Publicacion No 71 1946 42 pp. 32 figs

Several eruptions may be seen in patients infected by *T. cruzi* urticarial erythemas morbilliform rashes have been described but the present article illustrates other forms perhaps rarer certainly more distinct. Small, punched out ulcers may be seen on the foot lip and elsewhere. A good illustration shows the differences between these and the punched-out ulcer of American leishmaniasis. Crusted healing ulcers of the lips and face and papular eruptions of the face and neck are not uncommon another photograph shows a dense papular eruption of the thigh yet another a child with extensive impetigo-like lesions of the chin neck and chest. These lesions usually heal well under treatment with 7602 (Ac) Bayer but leave pigmented scars.

FEVERS OF THE TYPHUS GROUP

TORTING N H & SHEPARD C C The Preparation of Antigens from Yolk Sacs Infected with *Rickettsiae*. *Pub Health Rep* Wash. 1946 May 17 v 61 No 20 701-7 1 fig 11 refs

Three methods of preparing antigen from yolk sacs infected with *Rickettsia prowazekii*, *R. mooseri*, *R. rickettsii*, *R. burneti* and *R. orientalis* are described. It was found that no single method was satisfactory for all these species of rickettsiae. All the methods were modifications of Craigie's diethyl-ether method. The antigenic potency of the products was estimated by complement-fixation tests applied to the sera of guinea-pigs which had been immunized by homologous strains of rickettsiae. In all three methods homogenized yolk sac cultures were used. In Method 1 a 10 per cent suspension was shaken directly with one-and-a-half volumes of ether. In Method 2, a 10 per cent suspension was centrifuged to sediment the rickettsiae before treatment with ether and the rickettsiae were resuspended in one-tenth of the original volume of saline so there was a ten-fold concentration. In both of these methods when *R. prowazekii* and *R. mooseri* were dealt with, the final product contained large quantities of antigen released by the ether and contained in the supernatant fluid after centrifugation. With *R. rickettsii* much less of this soluble antigen was released, with *R. burneti* and *R. orientalis* there was no release at all but rather a loss of antigen. The methods therefore were quite unsuitable for the preparation of *R. orientalis* antigen.

In Method 3 the homogenized yolk sacs were shaken with 10 volumes of ether at a temperature of 4°C for 30-60 minutes. After standing for a short time the ether became yellow and a reddish mass of tissue fell to the bottom. The ether was decanted and fresh ether was added once or twice till it ceased to become yellow. After final decanting, about 1.0 cc. of distilled water was added for each gramme of yolk sac and after shaking the ether still in solution was removed under a partial vacuum. The suspension was kept overnight in a refrigerator and then centrifuged. The antigens were contained in the clear-red supernatant. In the case of *R. orientalis* the sediment also contained a considerable amount of antigen. By this method a satisfactory antigen was obtained from yolk sacs infected with *R. orientalis* the complement fixation titre was 1-128 as compared with one of 1-8 for the original crude 10 per cent suspension and titres of 1-2 for the preparations made by Methods 1 and 2. With *R. burneti* there was actually a loss of antigen when Method 3 or any other method of ether extraction, was used. With *R. rickettsii*, *R. prowazekii* and *R. mooseri* Method 3 gave much the same results as the other two methods. The titre with *R. rickettsii* was 1-32, with the other two organisms it was in excess of 1-2,048.

The authors state quite clearly that no demonstrable immunization has been produced in mice inoculated subcutaneously with any antigens prepared from yolk sacs infected with tsutsugamushi disease. *John H D Meyer*

TOPPING V H & SHEPARD C C A Method for the Preparation of Tsutsugamushi (Scrub Typhus) Antigen from Infected Yolk Sacs. *Pub Health Rep Wash.* 1946 May 31 v 61 No 22 778-81

This paper by the same authors as the one reviewed above was scheduled for publication on March 2 1945 but was withheld because of the subject matter. The method described has presumably been superseded by Method 3 dealt with in the preceding abstract but the paper will be of historical interest to all workers on the preparation of rickettsial vaccines.

John H D Megaw

CHALKE H D Typhus Experiences in the Central Mediterranean Force
Brit Med J 1946 June 29 977-80 July 6 5-8 1 chart & 1 fig

The author tells how the allied forces succeeded in keeping remarkably free from typhus fever during military operations in North Africa Italy and Yugoslavia in spite of the great prevalence of the disease among the people of these countries and in spite of the fact that none of the hygiene staff officers were informed of the projected landing in North Africa till the forces had actually embarked.

The preparations for dealing with the disease among the British troops consisted in the provision of large quantities of the powder A.L.63 (which contained derris and naphthalene) and of large numbers of portable disinfectors. Medical staff-officers were inoculated with a Cox type vaccine and talks were given before landing to officers and men.

After landing contact was made with the French Chief Officer of Public Health of Algeria who stated that between October 1941 and September 1942 nearly 40 000 cases of typhus fever had been reported and that he believed the real incidence to have been at least six times as high as this. One important safeguard was the fact that hardly any cases occurred in the large towns in which the people had been vaccinated by Blanc's liver murine vaccine. About two million persons had received this vaccine by the end of 1942. The killed vaccine of Durand and Giroud was used for doctors and others exposed to special risks and although there were many cases of typhus among the 71 000 persons who received the vaccine no deaths were known to have occurred. All the American troops had been vaccinated before landing but for the first few months the British troops were not protected in this way and they had to rely on regular hand-dusting with A.L.63 and on intensive propaganda. In 1943 there were about 34 cases of louse borne typhus and six of other forms of typhus among the British forces. When native-labour forces were enlisted, the recruits were bathed, disinfested, and inoculated with the Blanc vaccine.

The author tells the story of the much publicized epidemic in Naples. The city was occupied by the Fifth Army in October 1943 in November there were rumours that typhus was occurring and on investigation it appeared that the reports were well-founded. A conference of British and American hygiene officers was at once called this was attended by Italian public health doctors. A representative committee was set up a meeting of the medical men of Naples was held and prompt action was taken to search for cases and to disinfest all hospital patients and contacts.

From November 16 the incidence in successive weeks was —18 18 22, 45 and 36 cases then a sudden rise occurred in the week December 22 to 28 with 138 cases.

Early in December Dr Soper and Dr Davis of the Rockefeller Foundation arrived and by the middle of the month systematic case searching and widespread disinfestation of contacts with the American powder MYL (containing

pyrethrum) were in operation. An important point was the initiation of the system of disinfection by applying the powder with dust guns without removing the clothing by this method large numbers of persons could be disinfested as many as 60 000 were dealt with daily and by the end of February 1944 2,250 000 dustings had been carried out.

The U.S.A. Typhus Commission team arrived in December and began work early in January 1944. Details of the very thorough system of control established under the direction of the Commission have already been fully reported the operations were unprecedented, both in their magnitude and in the completeness of the organization. Large quantities of 10 per cent. DDT powder became available early in January.

The author states that the measures adopted up to December 23 had already brought the epidemic under control because after the week ending January 11 there was a sudden fall from 340 to about 170 in the weekly number of cases reported he assumes a time lag of about 18 days made up of the 12-day average incubation period and the average delay of six days in reporting the cases. This view will not be universally accepted there were still as many as 130 cases in the week ending February 8 and in the following week there was a sharp drop to 40 cases so that allowing for the same time lag it may be argued that control became really effective towards the end of January.]

The conditions prevailing in Naples at the time of the epidemic are described in vivid language they were such that a devastating epidemic would have been expected to occur during the first half of 1944 whereas the disease had disappeared from the city by the middle of April.

The remarkable results obtained are attributed to the perfection of the methods adopted and to the close and amicable co-operation between the British and American medical officers the U.S.A. Typhus Commission the Rockefeller Foundation team the Allied Commission the Allied Military Government the Italian civil and military doctors and the troops themselves.

The British troops and their attached civilian workers were protected only by MYL or A.L. 63 powder few of them were inoculated, yet only two or three cases occurred in this large group. The only British soldier attacked was a deserter who was heavily infested with lice. *John W. D. Meyer*

ZARAFONETIS C. J. D. ECKE R. S. YEOMANS A. MURRAY E. S. & SWYDER J. C. Serologic Studies in Typhus-Vaccinated Individuals. III. Weil-Felix and Complement Fixation Findings in Epidemic Typhus Fever occurring in the Vaccinated. *J. Immunology* 1946 May v 53 No 1 15-30 [17 refs.]

The authors working with the U.S.A. Typhus Commission in Cairo have studied the Weil-Felix and complement-fixation reactions occurring at various stages of attacks of typhus fever in patients who had been protected by an epidemic typhus vaccine of the Cox type. Of the 31 cases investigated 29 were diagnosed with certainty or with a high degree of probability as epidemic typhus the other two were cases of murine typhus contracted in West Africa. The conclusion was reached that the reactions can safely be used to establish a laboratory diagnosis of typhus fever in vaccinated persons provided that allowance is made for the higher degree of cross-fixation for epidemic and murine typhus that occurs among these persons as compared with unvaccinated patients. The paper is complementary to one by PLOTZ and WERTMAN who carried out similar tests on murine-typhus patients previously vaccinated with epidemic typhus vaccine see this *Bulletin* 1946 v 43 429.]

In all the 31 patients the rises observed in the titres of the Weil-Felix (O & I) and complement fixation reactions were higher than had ever been observed by the authors among healthy persons who had received "booster" doses of

the vaccine or among vaccinated persons who were suffering from other febrile diseases. In two of the 29 cases of epidemic typhus the murine-complement fixation titre reached the same high level as the epidemic titre but in most of the other cases the epidemic titre was four or more times as high as the murine.

Strangely enough the two patients diagnosed as having murine typhus had epidemic titres rising to 1-512 and 1-1 024 whereas their murine titre was only 1-256 in each case.

The authors suggest that the high degree of cross-fixation observed among vaccinated patients may be due to the presence of a common antibody produced in the serum in response to the action of the antigen common to epidemic and murine rickettsiae that is contained in the vaccine the common antibody would be expected to fix complement in the presence of antigens either of the epidemic or murine type.

Two of the patients suffered from laboratory infections the serum of one of these had given an epidemic typhus complement fixation reaction at a titre of 1-8 about two months before the onset and also on the second, third and fourth days of the illness the titre rose to 1-32 on the fifth day this patient's serum was known to have contained a considerable amount of neutralizing antibodies two months before the illness as shown by tests with gerbils so that the immunity known to exist beforehand had obviously not been enough to prevent infection but only to modify the severity of the attack.

John W D Megaw

SHEPARD C C & WYCKOFF R W G The Nature of the Soluble Antigen from Typhus Rickettsiae. *Pub Health Rep Wash.* 1946 May 31 \ 61 No 22 761-7 8 figs on 4 pls

With the help of the electron microscope the authors have investigated the physical characteristics of the filter passing soluble antigen which is liberated from suspensions of epidemic and murine rickettsiae by ether treatment. This antigen has now been shown to consist of sub-microscopic particles of a capsular substance which adheres to and partly envelops the rickettsiae contained in a suspension purified by centrifugation. The term droplets is also applied to the particles which, though not uniform in size are so small that most of them could pass through bacterial filters. A photograph at a magnification of 18 000 diameters shows clearly a large number of the rounded particles present in a film prepared by evaporating a minute drop of the supernatant fluid obtained by high speed centrifugation of warm-ether extracts of homogenized yolk sacs infected with murine rickettsiae. The dried films were shadowed " by coating them with an obliquely deposited film of gold by the method of WILLIAMS and WYCKOFF (*J of Applied Physics* 1946 \ 17 23).

Seven other photographs prepared on the same lines show (1) *R. prowazeki* and *R. mooseri* from untreated suspensions (2) *R. prowazeki* after extraction with ether and demonstrating that the liberation of the particles from the capsular substance is much more active and complete with warm-ether treatment than with cold-ether treatment and (3) clumps of particles of soluble murine antigen agglutinated by homologous immune serum of rabbits.

GIROUD P Démonstration faite au sujet des corps homogènes inclusions du typhus exanthématique [Demonstration of the Homogeneous Inclusion Bodies of Exanthematic Typhus.] *Bull Soc. Path Exot* 1946 \ 39 Nos. 3/4 83-6.

The author describes the results of further investigation into the various forms assumed by the rickettsiae of typhus fever and the products of their action on the invaded cells.

The bodies now described were obtained from animals whose initial resistance to infection was being broken down. Smears containing the bodies were fixed treated with acetone and stained by Giemsa's method.

Side by side with blue-staining homogeneous bodies other intracellular purple ('aubergine-coloured') rounded bodies of similar size were seen. On the surface of the latter there were one or more small masses of about one μ in diameter which gradually became transparent, lost their central portion and assumed the form of rings with one or more thickenings. At a later stage each ring broke into two or three parts, each of which at first consisted of a slightly curved rickettsia with pointed ends and later became like a normal bacilliform rickettsia.

Another transformation of blue-stained homogeneous bodies was sometimes seen in which they became broken up into transparent elements of three to four μ in diameter each containing an unstained vacuole which later showed a chromatin-stained particle in its centre. Sometimes each element contained three or four vacuoles of the same kind. Soon the appearance of the original homogeneous body became changed to one of an enlarging granular body resembling a compact swarm of bees.

The author regards the homogeneous bodies as analogous with bacterial spores and as being capable of giving rise to bacilliform rickettsiae in the ways described.

(For the earlier studies on this subject by the author and PANTHER, see this Bulletin 1943 v 40 784 and 1942, v 39 753.)

John W. D. Meager

CRAIGIE J. WATSON D. W., CLARK Ema M. & MALCOMSON M. Elizabeth.
The Serological Relationships of the Rickettsiae of Epidemic and Murine Typhus. *Canadian J. Res. Sect. E. Med. Sci.* 1946 Apr v 24 No 2 84-103 5 figs. (17 refs.)

This paper was submitted as a confidential document in September 1943. Breinl and Madrid strains of epidemic rickettsiae and the Castañeda strain of murine rickettsiae were used in the experiments which are described in detail by the authors.

Specific differences were shown to exist between the complement fixing antibodies of epidemic and murine rickettsiae by removing the antibody common to both types from immune sera by the addition of rickettsiae of the heterologous types. Sera treated in this way were tested by the complement-fixation reaction and gave much higher titres with the homologous than with the heterologous antigen.

The type-specific complement-fixing antigen was found to be inactivated by heating for one hour at a temperature between 56° and 65°C. and so was shown to be thermolabile. The thermostable antigen remaining after this treatment was found to be the same for both types of rickettsiae.

The Giroud rabbit skin reaction was found capable of being applied to differentiate between the specific heat labile antigens of epidemic and murine rickettsiae.

Small doses of murine or epidemic vaccines immunized mice against the toxic factors of homologous but not of heterologous rickettsiae. When these vaccines were heated to 56°C. for 45 minutes much larger doses were needed to immunize the mice and the resulting immunity was the same for heterologous as for homologous toxins.

From the above and other experiments it appeared that epidemic and murine rickettsiae contained a common thermostable antigen and that each of the two types of rickettsiae contained a type-specific thermolabile antigen.

The authors state that there seems to be full justification for the suggestion made by Felix that there is an analogy between the heat-labile and heat stable antigens of rickettsiae on the one hand and the Vi and O antigens of the typhoid bacillus on the other.

No claim is made that the findings described necessarily apply to every strain of the two types of rickettsiae the authors refer to the need for an antigenic analysis of intermediate strains.

Full details of these important experiments will be found in the paper

JOHNSON Mary B & DAMON S R The Serologic Diagnosis of Endemic Typhus III. The Incidence and Titer of Complement-Fixing Antibodies in Random Samples of the Population in Endemic and Nonendemic Typhus Areas. *J Lab & Clin Med* 1946 May v 31 No 5 550-51

Complement fixation tests were carried out for endemic typhus [presumably the murine type] on the sera of —(a) 500 persons who formed a random sample of the population of Houston County in southern Alabama where the disease is endemic and (b) 400 corresponding persons from Morgan County in northern Alabama where the disease is rare.

In the former group there were 58 reactions at titres of 1-4 or over in the latter there was only one positive reaction.

The titres observed were 1-4 to 1-16 in 41 of the 59 positive sera and 1-32 to 1-256 in the remaining 18.

The authors point out that these findings have an important bearing on the significance of the reaction as a diagnostic test for febrile diseases occurring in areas where endemic typhus is prevalent.

LE CHUITON F & BERGE C A propos de la présence d'agglutinines anti Eberth para A ou para B dans le sérum de sujets vaccinés au T.A.B. attentifs de typhus murin nautique [The Presence of Typhoid and Paratyphoid Agglutinins in the Sera of Murine-Nautical-Typhus Patients who had been Vaccinated with T.A.B Vaccine] *Bull Soc Path Exot* 1946 v 39 Nos. 3/4 103-10

Details are given of the results of repeated Widal and Weil-Felix tests carried out on 11 patients suffering from murine nautical typhus. Four patients taken at random were examined, and only three developed no agglutinins for typhoid or paratyphoid bacilli during the course of the attack.

In one group of seven cases the typhoid titre reached a maximum range from 1-80 to 1-10,240 and although the Weil-Felix titre was considerably higher in five of these it was the same (1-2 560) in one and lower (1-1 240) against 1-10,240 in another.

In another group consisting of two cases the titres with both typhoid and para A bacilli rose to 1-320 or over in one of these the typhoid titre reached 1-40 000 the para A titre 1-320 and the Weil-Felix titre 1-1,280 all on the 10th day in the other the corresponding titres were 1-320 1-640 and 1-320.

In the latest group, which also consisted of two cases the para B titres reached 1-160 and 1-320 respectively and the Weil-Felix titres were 1-640 and 1-10,240.

The diagnosis of murine typhus was regarded as certain in all the cases of the series blood cultures were sterile in every one and in several of them rickettsiae were isolated by guinea pig inoculation.

The author points out that the sera of typhus patients are well known to have an increased power of agglutinating numerous kinds of bacteria and that in febrile patients who have been inoculated with T.A.B. vaccine the Widal test is of little value in diagnosis.

LE GAC P. Etude sur le typhus tropical des savanes de la haute Côte d'Ivoire.
[A Study of Tropical Typhus in the Savannas of the Upper Ivory
Coast.] *Bull Soc Path Exot* 1946 v 39 Nos. 3/4 86-94

Since December 1941 the author has studied the seasonal outbreaks of "grippe" which occur in the Upper Ivory Coast in close association with the seasonal trapping or burning out of wild rodents by the indigenous population who greatly relish these animals as an article of diet. Certain tribes in the area regard the red rat (*Mus rufinus*) as responsible for the outbreaks of the disease and forbid the eating of its flesh. Several Europeans who have entered the affected areas or have come into contact with rats driven out by the prairie fires are known to have been attacked by the disease.

Louse transmission is regarded as unlikely on epidemiological and serological grounds. The occurrence of definite outbreaks and the absence of local sores are considered to be improbable in a tick borne disease and larval mites have not been found in the African savannas. For these reasons the author believes that the rat flea *Xenopsylla cheopis* is the most likely vector though he also argues that the infection probably enters the body through the mucosae especially by ingestion of food contaminated by the hands of the rat hunters or by the urine and faeces of infected rats.

Twenty-two cases of which one was fatal, were seen among Europeans. The rash is said to have been much less conspicuous than that of louse borne typhus and to have differed from the rash of the tick-borne disease in being restricted to the chest. The intradermal hypersensitivity test with formalized vaccine supplied by Durand and Giroud (presumably of the epidemic typhus type) was positive in 14 of the 16 patients tested during convalescence. The Weil-Felix responses were varied. From the tables it appears that the following reactions at titres of 1-100 or over were observed in 31 tests. With *Proteus* OX19 16 were positive (1-100 to 1-200) and of these 12 were positive also with *Pr* OXA. With *Pr* OXA 13 were positive (1-100 to 1-500) and 12 of these were positive also with *Pr* OX19. With *Pr* OX2 all were negative at 1-100 and only two reacted at 1-50.

No significant reactions were observed among Patas monkeys, guinea-pigs or rabbits inoculated by the intraperitoneal route and passage inoculations from these animals were negative even among rats. Sera of inoculated monkeys and rabbits agglutinated *Pr* OX19 at titres of 1-50 to 1-150 and *Pr* OXA at 1-20 to 1-150.

The author states that "the specific *Proteus* of the disease has not yet been demonstrated, but that the epidemiology, symptomatology and serum reactions suggest that the fever belongs to the group of tropical typhus fevers (type scrub typhus of Malaya).

of rickettsiae contained cells with investigations carried out in 1938 and a letter

Guinea-pigs inoculated with the blood of infected persons had a febrile reaction lasting four or five days after an incubation period of about ten days but there was no scrotal reaction.

The fever is said to correspond in severity to louse-borne typhus and it is estimated that 2 000 to 3 000 persons die yearly in the area between the Cameroon border and the Anglo-Egyptian Sudan.

[The special interest of this and the preceding paper is that they contain evidence of the widespread occurrence in tropical Africa of a fever of the typhus group which appears to be primarily a disease of animals of the wilds. Although much of the evidence points strongly to flea transmission the serological and experimental findings are not such as would be expected in flea borne typhus. The author's suggestion that the disease should be classified as tropical typhus is not happy but there will be general agreement with the other suggestion that more research is needed to solve the problem of the transmitting vector.]

Observations on Tsutsugamushi Disease (Scrub Typhus) in Assam and Burma. Preliminary Report. *Amer J Hyg* 1946 May v 43 No 3 195-218 4 figs (1 map) [21 refs]

This paper is a preliminary report by a team of 14 workers of the U.S.A. Typhus Commission into the epidemiological and other conditions connected with the occurrence of mite-borne typhus in the China Burma India theatre of war from December 1944 to November 1945. The workers acknowledge the great assistance received from American and British voluntary helpers.

Towards the end of 1943 the disease was recognized as a serious military problem for the troops engaged in exercises and operations on the Assam Burma frontier and in Burma. From early November 1943 till early September 1945 there were 1 098 cases among American and Chinese troops with a case-fatality rate of 8.9 per cent. There were five peaks of incidence these at first suggested that there was a pronounced seasonal rise in spring and autumn but they were found to correspond with periods of combat and with training operations in special areas. For example in January 1945 there were 65 000 U.S.A. troops in Assam and Burma, yet of the 194 cases in that month all but nine occurred among 6 000 troops engaged in combat.

Certain outbreaks among Chinese troops appeared to be associated with the habit of bathing in a river on whose grassy banks the soldiers spread out their 10th day dry, and in one such locality the grassy ground was found heavily

In the latest group winter also consists by the Chinese troops was also reached 1-160 and 1-320 respectively and the well road from Ledo in

The diagnosis of murine typhus was regarded as certain 13 genera of the series blood cultures were sterile in every one and in 45 new rickettsiae were isolated by guinea-pig inoculation.

The author points out that the sera of typhus patients are weakly agglutinated by a small number of agglutinating numerous kinds of bacteria. In febrile patients who have been inoculated with T.A.B. vaccine the test is of little value in diagnosis.

John W. D.

flavipectus yunnanensis and (4) 4 from the tree shrew *Tupaia belangeri* *retzius*. Three strains were isolated from laboratory white rats, and one from the pooled tissues of 4 gerbils which had been experimentally exposed to mite attacks in endemic regions. The preponderating mite was *Trombicula deliensis* which was the only mite found in 24 of the pools from which infection was isolated and which was present in every one of the positive pools.

Transovarial transmission of *R. orientalis* was demonstrated by hatching, in the laboratory, eggs of *T. deliensis* from infected localities and causing the larvae to feed on susceptible animals.

Incompletely engorged mites sometimes became detached from the initial host and afterwards completed their meal on another animal. In four experiments with *T. deliensis* the reattached larvae caused infection in laboratory animals.

The rat and tree shrew already mentioned were the only mammals found naturally infected though three strains were recovered from mites obtained from Sladen's roof rat (*Rattus rattus sladeni*). A complete investigation of the numerous animal hosts of *T. deliensis* was impracticable.

In the three areas along the Stilwell Road in which hyperendemicity was indicated by exceptionally high attack rates among troops *T. deliensis* constituted 60.74 and 98 per cent respectively of all the mites collected. A high incidence of this mite therefore indicates that the area should be strongly suspected. There was also evidence that areas in which cases of the disease have occurred remain risky for at least one year. *John W D Megaw*

VAN DEN ENDE M LOCKET S HARGREAVES W H NIVEN J & LEMMHOFF
L. Accidental Laboratory Infection with Tsutsugamushi Rickettsia.
Lancet 1946 July 6 4-7 4 charts.

In spite of the strictest precautions four persons became infected with tsutsugamushi disease in the course of work connected with the large-scale production of vaccine made from the lungs of cotton rats [see this *Bulletin* 1946 v. 43 435 and 436]. All the patients had been protected by Fulton and Joyner vaccine of the cotton-rat lung type. The duration of the fever was 14-16 days in three of the cases and at least 19 days in the fourth. One of the patients became "critically ill on the sixth day" when she had a faint heliotrope cyanosis; another was very ill on admission and thereafter her mental and physical condition deteriorated till she became unable to take fluid by the mouth. The other two patients do not seem to have been dangerously ill at any stage of the disease. All the patients made good recoveries, and the authors conclude that as there were three deaths among five previous patients known to have had laboratory infections with *Rickettsia orientalis* the vaccine may have had significant value in protecting against death.

From the details supplied of the clinical features of the attacks it appears that these conformed with those often observed in the naturally acquired disease. Delirium was severe in one case and mild or very slight in the others. In three cases there was a local lesion at the site of infection [see p. 436]. In two of these there was an associated local adenitis. Numerous other repeated falls of the temperature were features of two cases in which the fever curve was of the continued type.

The Weil-Felix (OAK) reaction was positive in every case to a fever which maximum titre was only 1-160. This was reached on the day the disease described. *Rickettsia orientalis* was isolated from the blood taken on the sixth day. In the Equatorial Africa peritoneal inoculation of mice and guinea-pigs. In an experiment with rats which swarmed were isolated from blood taken on the sixth day. The blood contained numerous fleas

Infection of the different patients occurred in the following ways—(1) From a prolonged bite by a cotton rat which had just received intranasal inoculation the incubation period was 14 days (2) Probably by droplet infection occurring in the course of work which involved the transfer of virulent lung suspension by a Pasteur pipette from centrifuge tubes to ampoules. By actual test it was found that bubbling with the discharge of droplets into the air was almost unavoidable during this procedure (3) By a puncture of the skin through a rubber glove with an accidentally broken pipette which had just been emptied of a virulent suspension of the rickettsiae. A tourniquet was applied within half a minute the wound was excised within five minutes bleeding was encouraged and antiseptics applied. An injection of 1.0 cc. of vaccine was given at once and on the same day 10 cc. of phenolized serum from an immunized rabbit was injected. On the next day 12 cc. of phenolized serum from a patient in the third week of convalescence was injected intramuscularly. The incubation period was 11 days (4) Through washing by hand Petri dishes which had contained infected cotton-rat lungs. This action was in gross contravention of the rules so the patient did not report the occurrence. The incubation period was about 17 days according to the statement made later by the patient

SMADEN J. E., RIGHTS F. L. & JACKSON Elizabeth B. Studies on Scrub Typhus. II. Preparation of Formalinized Vaccines from Tissues of Infected Mice and Rats. *Proc Soc Exper Biol & Med* 1946 Mar 1 61 No 3 308-13 1 fig

The authors mention the interesting fact that after a number of unsuccessful attempts to produce a potent inactive vaccine against scrub typhus three promising methods have been reported almost simultaneously. These were as follows in brackets are the dates of the original confidential reports in which they were first described—(1) FULTON and JOYNER's rodent-lung vaccine (June 21 1944) [see this *Bulletin* 1946 1 43 435] (2) A tissue-culture vaccine of PLITZ and his co-workers (September 23 1944) [see the abstract immediately following this] and (3) A rodent tissue vaccine (October 2, 1944) as described in the present paper

White mice white rats or cotton rats were inoculated intravenously with suspensions of infected yolk sacs the estimated dosage was 10^4 M.L.D. of *R. orientalis*. On the 4th or 5th day the animals were moribund or dead their lungs and spleens were homogenized and a 10 per cent suspension in normal saline was prepared and freed from large particles by centrifugation. Formaldehyde (0.1 per cent) and merthiolate (0.01 per cent) were added and the suspension was stored at 5 C for 1-6 weeks. The strength in complement-fixing antigen was titrated, though it is stated later that the potency of the vaccine could not be estimated by this procedure.

Groups of 24-70 mice were inoculated intraperitoneally with three doses of 0.5 cc. of the vaccine at five-day intervals. After two weeks the mice were challenged with varied doses of homologous rickettsiae. Large numbers of mice had to be used because of the wide range of individual susceptibility of the animals. Details are given of the results of the tests and of the standards used in estimating the degree of immunity produced by the vaccine. *R. orientalis* was used in preparing white-rat vaccine till it was found that the area measurable of growth in a highly infective condition in yolk sacs. The northern Assam strain of yolk-sac suspensions was easily estimated by observing the death of white mice injected intravenously with 0.5 cc. of a suspension. White rats were used for the preparation of the vaccine. The following strains of *Gerbillus gerbillus* were found to give a large yield obtainable from each animal this amounted to 53 from pooled suspensions.

The authors regard their method as being preferable to the cotton-rat-lung method because bacterial sterility was not a problem intravenous injection is safe and simple and white rats are easier to obtain and handle than cotton rats.

The vaccines obtained by the three methods mentioned above are said to be of comparable potency but all are regarded as being difficult to exploit on a large scale.

John W. D. Megaw

Plotz H. BENNETT B. L. & REAGAN R. L. Preparation of an Inactivated Tissue Culture Scrub Typhus Vaccine. *Proc. Soc. Exper. Biol. & Med.* 1946 Mar. v. 61 No. 3 313-17

Yolk-sac cultures of *Rickettsia orientalis* were obtained from peritoneal exudate of infected mice and used in the preparation of tissue cultures by the method of Zimmer Plotz and Enders. The early yolk-sac cultures were poor in rickettsiae but by selection and repeated passages a rich growth was eventually obtained and this was found suitable for the preparation of satisfactory tissue cultures which constituted the vaccine. Full details of the method are found in the paper.

Some of the vaccines were of low potency when this happened it was found that the culture flasks had not been adequately examined to ascertain their richness in rickettsiae. The most potent vaccines had an immunity index of 3.7 to 4.5 logs in other words they induced protection against from 5,000 to 32,000 M.I.D.s of *R. orientalis*.

In one series of experiments mice received "booster" doses of vaccine and the induced resistance was greatly increased for example up to 7,800 to 80,000 M.I.D.s. This and the other two vaccines referred to in the preceding paper were regarded as being of comparable potency but the immunity conferred on white mice by all three vaccines was obtained only by the use of intraperitoneal inoculations never by subcutaneous injections.

It is admitted that the large-scale preparation of vaccine by the tissue culture method "would present certain technical difficulties" but for the protection of selected personnel it has the advantage of being a relatively clean product.

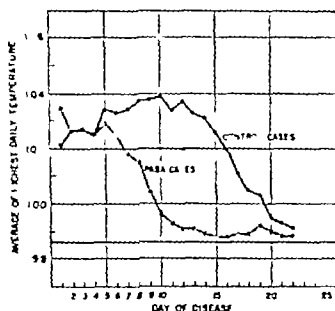

The yolk-sac method, which would be the most suitable for mass production has never been successfully prepared one reason being the deleterious effect of ether upon the antigen.

John W. D. Megaw

TIERNEY N. A. Effect of Para Aminobenzoic Acid in Tsutsugamushi Disease. *J. Amer. Med. Ass.* 1946 May 25 v. 131 No. 4 280-85 2 charts. [10 refs.]

Strikingly good results were obtained from the administration of para-aminobenzoic acid (PABA) in the treatment of 18 scrub-typhus partly acquired American and Indian military hospitals at Ledo Assam. Therapeutic effect in these cases and almost without exception alternately admitted upon [see below] and in each hospital.

The chart shows that the average duration of the feases in the other two longer in the control group than in the treated. In three cases of the fever and symptoms occurred after the in every case in one the this second spell of fever lasted three to 14 days ended on the fourth day and R. ill and no further doses of the drug were given on the second day by intra the general symptoms were pronounced ways. In another case the organisms became alert and the headache disappeared day.

Comparison of the average of the highest Fahrenheit temperature each day in 18 untreated control cases of scrub typhus and in 18 cases treated with para-aminobenzoic acid (PABA)

[Reproduced from the *Journal of the American Medical Association*.]

the treated had slight bronchitis whereas 14 of the controls had severe bronchitis. Full details are given in tabular form of the chest findings in the two groups of patients. The general results are shown in the following table —

Severity of the Attacks among Treated and Controls

	Mild	Moderate	Severe	Grave	Fatal
Indian treated (9)	8	1	0	0	0
American (8)	4	3	0	1	0
Chinese (1)	0	1	0	0	0
Total (18)	12	5	0	1	0
Controls (16)	1	1	4	7	3

The treatment was started on the 3rd day in four cases on the 4th day in five on the 5th day in three on the 6th day in four, and on the 7th day in two.

The drug was given by the mouth as a powder to each gramme of which a 5.0 per cent solution of bicarbonate of soda was added. The dosage challenged most effective was 8.0 gm. initially followed by 3.0 gm. every two hours. The total dose was 217–357 gm. for Indian and 217–513 gm. for American.

Details of the drug in the blood was determined by the Marshall method as used for sulphanilamide [see *Science* 1938 July 22 85]. The area of *R. s. s.* was 30–60 mgm. per 100 cc. but when the patients became anemic of growth was often reduced to 10–20 mgm. without recrudescence. The following strains of *G. m.* were found. White rats (56 mgm.) this difference suggests that the body of *G. m.* was not have been sufficiently taken into account. Two (2) 53 from pooled suspension.

of the Indian patients who had very high maximum concentrations of 152 and 155 mgm are said to have suffered from "confusion due to PABA" and the patient whose maximum concentration of 103 mgm. was the highest among the American group suffered from convulsions.]

There was a general tendency to leucopenia towards the end of the course of treatment—total counts of 4 000 per cmm or less were observed in nine of the treated and in only two of the controls. There was a satisfactory return of the leucocyte condition to normal in every case and the treatment was never curtailed because of leucopenia. It is recommended that the total white cell count should be determined every other day—if it falls below 4 000 a differential count should be made and if the granulocytes are less than 30 per cent. the drug should be discontinued. A total count of less than 3 000 is in itself a contraindication.

It is advised that when the blood concentration of the drug exceeds 60 mgm per 100 cc one dose should be omitted and the maintenance dose should be suitably reduced. The treatment should be started as early as possible but it may be worth trying even after the end of the first week. Sulphonamides are regarded as being contraindicated—bacterial complications should be treated with penicillin.

The diet of the treated and control patients was rich in proteins, calories and vitamins. 4.0 gm. of additional sodium chloride was given and the fluid intake was 3–4 litres daily.

In view of the results obtained in the present trials taken in conjunction with those reported by YEOMANS and his co-workers in louse borne typhus [see this *Bulletin* 1945 v 42: 201] and the abundant evidence supplied by animal experiments the authors think it likely that PABA may prove to be a general anti-rickettsial drug.

John W. D. McGraw

ZARAFONETIS C. J. D. SNYDER, J. C. & MURRAY E. S. Immunity following Para-Aminobenzoic Acid Therapy in Experimental Tsutsugamushi Disease (Scrub Typhus). *Proc Soc Exper Biol & Med* 1946 Mar v 61 No 3 240–42 [Refs. in footnotes]

Gerbils which had recovered from experimental infection with the rickettsiae of tsutsugamushi disease with the help of para-aminobenzoic acid (PABA) were tested six to nine months later and found immune to three different strains of *Rickettsia orientalis* administered by the intraperitoneal route in doses ranging from 2,140 to 31 600 lethal doses. There was only one death among the 69 gerbils used in the test. Ceylon, Calcutta and Karp strains of *R. orientalis* were used to infect different groups of the gerbils and the animals belonging to each group were divided into three subgroups, one of which was challenged by the homologous strain of rickettsiae and the others by heterologous strains. Complete immunity was found to exist irrespective of the strains used in the original infection and the immunity tests so that cross immunity had obviously been produced. The findings were regarded as showing that the action of PABA is to inhibit the growth of rather than to kill, the rickettsiae.

BUSHLAND R. C. Tests against Chiggers in New Guinea to develop a Practical Field Method for Impregnating Uniforms with Dimethyl Phthalate for Scrub Typhus Prevention. *Amer J Hyg* 1946 May v 43 No. 3 219–29

Trombiculid mites are a serious nuisance in many temperate and tropical regions as well as being the vectors of scrub typhus. Some protection may be obtained in many ways, the most familiar being by dusting the socks and garments with sulphur but this is not reliable enough when dealing with scrub

typhus. Experiments were carried out in New Guinea using the larval mites *Trombicula buloensis* and *Schöngastia pusilla* which appear to be similar in their reactions to the actual vectors of scrub typhus (*T. fletcheri* and *T. walchi* have been incriminated) which cannot be obtained in sufficient numbers for experiments. [It will be remembered that PHILIP *et al* (this Bulletin 1946 v 43 733) regard *T. fletcheri* and *T. walchi* as synonyms of *T. akamushi* and *T. deliensis* respectively]

Garments were impregnated in bulk with an emulsion of 5 per cent dimethyl phthalate 2 per cent soap and water. This could be made up without any special apparatus and after drying it left about two ounces of dimethyl phthalate in each set of garments. This gave no discomfort except a slight burning sensation in the scrotum which was prevented by using untreated underpants.

The garments were tested by placing live mites on the material and measuring the stopping time i.e. the time taken to paralyse the mites. If this occurred in less than 15 minutes then the garment was considered protective. Volunteers also exposed themselves in areas where mites caused scrub itch but from which typhus was believed to be absent. Impregnation gave almost complete protection up to five weeks if the garments were not laundered and it withstood some rinsing in cold water but protection was lost after proper laundering or after long wading in fresh or salt water.

Kenneth Mellanby

BUSHLAND R. C. New Guinea Field Tests of Uniforms Impregnated with Miticides to develop Laundry-Resistant Clothing Treatments for preventing Scrub Typhus. *Amer J Hyg* 1946 May v 43 No 3 230-47

It has been shown [see BUSHLAND above] that uniforms impregnated with dimethyl phthalate give good protection against trombiculid mites but that this protection is lost after the garments are laundered. Other substances toxic to mites were tried and dibutyl phthalate and benzyl benzoate gave the best results. The benzyl benzoate impregnated from a soap-and-water emulsion at the rate of two ounces per fatigue uniform (jacket trousers socks) gave practically complete protection until the garments had been laundered three times at 210°F. Dibutyl phthalate was less effective at the outset but it withstood washing better. A mixture of equal parts of benzyl benzoate and dibutyl phthalate is advocated.

Kenneth Mellanby

HARRELL G. T. WOLFF W. A. VENNING W. L. & REINHART J. B. The Prevention and Control of Disturbances of Protein Metabolism in Rocky Mountain Spotted Fever. The Value of Forced Feedings of a High-Protein Diet and of the Administration of Specific Antiserum. *Southern Med J* 1946 July v 39 No 7 551-7 1 fig

Nine children suffering from Rocky Mountain spotted fever were treated with a diet containing about twice the amount of protein present in the standard hospital diet. When necessary supplementary feeds of high protein liquids were given by gavage so as to bring up the total quantity of protein to 4.0 gm per kilo of body weight.

The general condition of the patients was observed to be much better than that of eight patients previously treated on the usual dietary. Oedema was less and there was a gain in weight during the illness in nearly every case. The serum proteins were maintained at slightly higher levels and there was evidence that the body proteins were being depleted to a less degree.

GLASGOW R. D. & COLLINS D. L. Control of the American Dog Tick, a Vector of Rocky Mountain Spotted Fever. Preliminary Tests. *J. Econom. Entom.* 1946 Apr v 39 No 2 235-40 2 figs.

In recent years tick-borne Rocky Mountain spotted fever has been troublesome in parts of South-eastern New York State. The vector is the American dog tick *Dermacentor variabilis*. The cases which have occurred are deterring people from using the recreational facilities which exist in this area and the public health authorities are anxious for control measures to be devised as quickly as possible. In 1945 preliminary work was done with several insecticides of which DDT, gammexane, pyrethrins, rotenone and nicotine appeared to be promising. Lethane 384 Special and Halowax (chlorinated naphthalenes) were less effective. Mixtures were also tried, and one promising formula was 0.25 to 0.5 per cent DDT plus 0.08 to 0.125 per cent pyrethrins. 2 quarts of this were used per acre. For application the insecticides were dissolved in fuel oil or diesel oil, and were atomized by a paint sprayer connected to a mechanical compressor. It was proposed to try sprays applied by aeroplanes and aerosol fogs from thermal generators, for making large scale treatments. More extensive work was planned for 1946. *J. R. BURRIS*

IRONS J. V. TOPPING N. H. SHEPARD C. C. & COX, H. R. Outbreak of Q Fever in the United States. *Pub Health Rep. Wash.* 1946 May 31 v 61 No 22, 784-5.

An outbreak of more than 40 cases in March 1946 with two deaths in stock yard men in Texas. Investigations suggest that cattle are involved in the human infections. Clinical and serological evidence is in favour of Q fever, high complement fixation titres to Q fever antigens being found in sera from convalescents and rickettsia-agglutination tests being positive. The illness varied from mild fever to severe pneumonitis. *Charles Wilcocks*

YELLOW FEVER.

GAST-GALVIS A. Viscerotomy en Colombia. [Viscerotomy in Colombia.] Reprinted from *Rev. Medica*. Bogotá. 1945 Sept. & Oct. Nos. 553-554. 34 pp. 4 figs. 3 maps & 1 graph. [12 refs.] English summary.

The Colombia Viscerotomy Service was started in September 1934 and now there are 200 viscerotomy centres and the number of specimens taken has reached 22,000. When first started the object was to find, from examination of liver tissue, the prevalence of yellow fever, but the value of the procedure is not so restricted and in this article the author records the findings in other diseases also such as malaria, sickle cell trait, cirrhosis, acute yellow atrophy, tumours, etc. Of the 22,000 specimens taken, 7,302 were from children up to 4 years of age and 1,927 from those between 5 and 9 years; i.e. 9,229 (42 per cent. of the total) from those under 9 years. Among the specimens 352 showed the changes of yellow fever, over 90 per cent. of these were from males and 136 (38.6 per cent.) were in the third decade; only 7 were from females.

Of other diseases diagnosed from viscerotomy specimens there were 2,447 cases (11.1 per cent.) of malaria (i.e. malarial pigment was present) most coming from the Magdalena Valley. Forty-three men and 28 women showed signs of sickle cell trait. Pathological changes of acute or subacute yellow atrophy of the liver were found in 175 subjects. Most of these came from the Bananera Zone of Magdalena, the next highest being the

south-west of Antioquia. Tuberculosis was seen in 391 specimens 116 (29 per cent) of which were from children under the age of 5 years and 115 from persons over 40 years. Signs of cirrhosis were present in 404 that is less than 2 per cent and syphilitic changes in 10 only. Thirty five showed tumours—adeno-fibroma (1) metastatic adeno-carcinoma (16 male 7 female 9) and sarcoma (2). One case of visceral leishmaniasis was seen in Santander Department the first to be diagnosed in Colombia.

DENGUE

DIAZ RIVERA R S A Bizarre Type of Seven Day Fever Clinically Indistinguishable from Dengue *Bol Asoc Med de Puerto Rico* 1946 Mar v 38 No 3 75-80 7 figs. on 2 pls

[A contradiction in terms is contained in the title of this paper if the disease is indistinguishable from dengue it cannot well be called a bizarre type of seven-day fever]

The only important respects in which the authors regard the disease as differing from dengue are the absence of leucopenia and bradycardia but the evidence in support of the existence of these differences is not convincing. The total leucocyte count is stated as ranging from 3 000 to 7 200 per cmm. and as the days of the disease on which the counts were made are not stated these figures are by no means inconsistent with the diagnosis of dengue there may have been a fall in the count during the illness. The leucocyte picture in other respects is suggestive of dengue since a definite lymphocytosis was observed in every instance. It is also stated that in at least 26 of the 58 cases seen at San Juan Puerto Rico there was a tendency towards bradycardia.

Some of the chief features of the disease were—a duration of six days with sudden onset accompanied by aches and pains and retrobulbar pain in every case. There were severe body pains in 70 per cent a rash conforming to one of the types seen in dengue in 53 per cent. a biphasic fever curve in 70 per cent. and lymphadenopathy in 27.6 per cent. of the cases. The termination was by crisis or rapid lysis. It is stated that the vector and the other conditions favourable to the transmission of dengue were present. In view of these observations and of the absence of any other explanation of the outbreak it seems strange that there should have been any hesitation in regarding the disease as dengue.

It is also stated that Dr W H. Glines of the City Hospital, San Juan claims that dengue has been occurring in the locality "since the early thirties."

John B D Megaw

BULL. U.S. ARMY MED DEPT 1946 July v 6 No 1 4-5 Effective Vaccine against Dengue Fever

In this short note it is stated that an effective vaccine against dengue has been obtained from a strain of the virus isolated in Hawaii. This strain has undergone 32 passages through the brains of mice and has lost its power to provoke but not to prevent typical dengue.

Charles Wilcocks.

POLLARD M LIVESAY H R WILSON D J & WOODLAND J C. Immunological Studies of Dengue Fever and Colorado Tick Fever *Proc Soc. Exper Biol & Med* 1946 Apr v 61 No 4 396-8 2 figs.

The authors have obtained experimental evidence which suggests that there is no immunological relationship between the agents of Colorado tick fever

and dengue fever. Their findings confirm those already reported by FLORE and his colleagues [this *Bulletin* 1946 v 43 737].

Two volunteers were inoculated with the virus of Colorado tick fever—one reacted with a typical attack, the other was found to be immune as the result of an experimental attack which occurred five months previously. Both of these persons 27 days after the defervescence of the one who was attacked and a normal volunteer were inoculated intradermally with serum from a dengue patient. All three responded with clinically typical dengue.

Two other volunteers were inoculated with dengue serum, and six days later had attacks of dengue-like fever lasting six days. Twenty-seven days after defervescence these persons and a normal volunteer were inoculated with the virus of Colorado tick fever. All three reacted with typical attacks of the disease.

The clinical features of the experimental attacks of the two diseases were remarkably similar except that no rash occurred in any of the cases of Colorado tick fever. The authors point out that different strains of the same disease agent may vary to some extent in their immunological properties so that if other strains had been used the results might not have been the same.

In spite of the obvious clinical relationship between the two diseases it would hardly be expected that they should be immunologically identical, in view of their being transmitted by different vectors—one case from man to man and in the other presumably from a lower animal to man.]

The authors refer to Bullis fever which like Colorado tick fever is associated with tick bite—they state that its aetiology appears to be different and that a further paper on the subject is in the press—they also promise a paper on the absence of immunological relationship between Bullis fever and dengue.

PLAGUE.

MAGROT E & BRISON J. A propos d'une épidémie de peste dans un élevage de cobayes. [Plague Epizootic among Breeding and Experimental Guinea-pigs.] *Bull. Soc. Path. Exot.* 1946 v 39 Nos. 3-4 119-21.

An account is given of an epizootic of plague among laboratory guinea-pigs in the course of an epidemic of plague in which rats were the source of the infection. There were peculiarities in the epizootic which seem to have some significance. At first it was not recognized to be plague. On autopsy the guinea-pigs presented no characteristic lesions of organs, cultures were negative and microscopic examination of spleen smears showed only small round corpuscles some of which stained solid and some were vacuolated. These rounded bodies were Gram-negative and it was not until the epizootic became more fatal that typical bacillary forms of *P. pestis* appeared and cultures became positive. The authors put out the suggestion that these rounded bodies may be the only forms of *P. pestis* present in diagnostic smears of lymph nodes in the benign forms of plague and at the end of an epidemic. Cultures of the corpuscular forms when obtained, took some 6 to 8 days to appear at room temperature.

MAGROT E. Le traitement de la peste bubonique par les sulfamides (sulfadiazine) [Treatment of Plague by Sulphadiazine.] *Bull. Soc. Path. Exot.* 1946 v 39 Nos. 3-4 113-19.

That the epidemic was due to a virulent strain is apparent from the facts that all untreated non-vaccinated persons died, and that inoculated guinea-pigs

died in 30 hours. Treatment apart from adjuvant and symptomatic therapy consisted of antiplague serum or sulphadiazine. Penicillin had proved useless experimentally in guinea-pigs and was therefore not tried. The sulphadiazine was given orally every four hours day and night in a large volume of liquid, with at least 20 gm. sodium bicarbonate daily to keep the urine alkaline. Originally the dose of sulphadiazine was 24 or even 30 gm. on the first day and this was gradually diminished during 10 to 15 days. The first dose was subsequently reduced to 24 or 21 gm. Treatment with serum alone appeared unavailing and there seemed to be little distinct advantage in combining serum with the sulphadiazine. Of the 28 persons treated with sulphadiazine two died a case mortality rate of only 7.14 per cent.

CHOLERA

GREIG, E. D. W. The Treatment of Cholera by Intravenous Saline Injections with particular reference to the Contributions of Dr Thomas Aitchison Latta of Leith (1832). *Edinburgh Med J* 1946 May, 53 No. 5 256-63. [18 refs.]

There are many reminders in this article of how our standard therapy has been built up or originated. Transfusion of saline solution in cholera was introduced to the profession by Doctor Latta of Leith when cholera reached Edinburgh from Newcastle early in 1832. The pandemic had started in Bengal in 1817 and for the first time reached Europe. It is sometimes difficult to follow the reasoning for old-time methods of treatment and this is illustrated here by reference to such therapy for cholera as actual cautery, bastinadoing the feet, suffocating under a feather bed. The treatment introduced by Dr Latta against considerable opposition however was based on scientific argument. He had read a report by O'Shaughnessy in the *Lancet* of the analysis of blood in cholera patients showing the great loss of water and of its neutral saline ingredients. After several trials he decided to supply the deficiency direct into the circulation and he described his solution as artificial serum. It was prepared by saturating water with protoxide of nitrogen holding in solution half a drachm of muriate and eight grams of subcarbonate of soda to the pound (pint) of water. Other details were included in the treatment which we have learnt to know as important. He used vapour baths to maintain the body temperature and recommended that the injection fluid should have a temperature of 112°F because 100°F is too low. The effects on the patient were dramatically favourable—on the pulse, the cramps, the temperature, the respiration, the countenance, the anxiety, the thirst and the secretion of urine. In all 156 cases of cholera were treated and 25 recovered. None would it is considered have recovered otherwise. There is much else of historical interest in this article and honour is also done to the collaborators of Dr Latta, to whom it is fitting that we should pay tribute for the wisdom that they taught us. [This paper is also a pleasing contribution to medical literature and throws an interesting sidelight on some aspects of the medical background of the early nineteenth century.]

W. F. HARRY

seasonal swing and the organism can persist on the surface only during the rainy season. In drier climates treponemata appear more abundantly in the axilla popliteal space perineum and external genitalia. Lesions of the mucous membranes which were rare as long as the skin lesions were florid become more numerous in these conditions appearing as mucous patches snail tracks or kidney-shaped ulcers on the fauces palate or pharyngeal wall. Such is the treponematoses of Arabia and mountain areas today whilst Ramsay in Assam observed 20 years ago that heat and moisture appeared to be the main factors in producing the characteristic lesions of treponematoses in that area.

Treponematoses did not remain confined to torrid zones. During its migration north its character altered by changing its pattern from a juvenile non-venereal disease to one of adult venereal infection. The forces of environment made it difficult for the parasite to remain confined to the skin, and drove the eruption towards the mucosa of the mouth and vagina. In this manner sexual intercourse afforded the common channel of infection.

In a specially important section labelled *Christopher Columbus* the author pours scorn on the familiar recapitulated tale of the introduction of syphilis from the New World. It is argued that the evidence in support of this story is very weak and that it is absurd to suppose that by action of the comparatively small number of suspects involved, the seeds of an epidemic of syphilis of such magnitude or of such virulence could have been sown. Arguing from analogy is at best a risky procedure but the author is not deterred by this, and refers to the accepted views on the genealogy of the horse from *Eohippus* on which the evolutionary development of the modern animal is generally based. In much the same way all the intervening and transitional steps between yaws and paresis can be demonstrated in European history within the compass of a few centuries.

The remainder of this exhaustive paper is replete with the oft-quoted distinctions between yaws and syphilis the trend of which is to back up Jonathan Hutchinson's dictum whenever an Englishman contracts yaws abroad he comes home with syphilis.

A similar attitude is adopted in the consideration of pinta which is regarded as the depigmentation commonly associated with syphilis and yaws. The parasite *T. carateum* is indistinguishable either from *T. pallidum* or *T. pertenue*. Pinta starts out exactly as many other cases of juvenile treponematoses. It is not true to state that it is confined to Central and South America as it would seem that this depigmentation is prevalent in the whole American hemisphere. Lieberthal has found three cases in Chicago and it is reported from the Argentine. American observers in Guam are finding it there now. Therefore pinta may occur anywhere where there is treponematoses especially of the juvenile and untreated type. That aortitis adenopathy juxta-articular nodules and other late signs of spirochaetosis are found in association with pinta is considered sufficient to clinch the argument.

Finally there are four considerations which recommend the author's views of acceptance of treponematoses as a world-wide disease. The first is a classification of nomenclature by resolving several diseases into one. This is a usual procedure as exemplified in other diseases such as tuberculosis in its various manifestations plague (sylvatic and human) borreliosis (tick and louse-borne) and yellow fever (jungle and urban African and American). Such classification has resulted in a better understanding of these diseases.

Secondly the comprehensiveness of treponematoses tends to produce a new and less provincial attitude.

Thirdly research in treponematoses is now handicapped by compartmental thinking and the assumption that yaws and syphilis are different diseases is a

barrier to any comprehensive programme. Yaws has much to offer as a field for study of the ecology and biology of the treponema.

Lastly if treponematoses is a disease of all mankind it should be recognized as such by epidemiologists, health officers, social hygienists and civil governments and such questions as sanitation, social habits, economics and laws are involved. Different educational procedures should be integrated. It is an illusion to hope for a syphilis-free civilization while yaws remains rampant in wide areas of the world.

[We have presented the author's views in an unbiased manner. He acknowledges himself quite patently as a disciple of that staunch unitarian, the late Admiral Charles S. BUTLER whose *Syphilis Sive Morbus Humanus* (1941) is so well known. No doubt equally cogent arguments can be advanced against this view. But that the present affords a good occasion to review the subject as a whole which has been so thoroughly and eloquently done in this treatise there can be little doubt.]

FLOCH H. & DE LAJUDIE P. Traitement pratique du pian par la pénicilline en suspension dans l'huile d'olive. [Treatment of Yaws by Penicillin suspended in Olive Oil.] *Institut Pasteur de la Guyane et du Territoire de l'Inini*. Publication No 115. 1945 Oct. 8 pp.

Solutions of sodium penicillin in distilled water in saline or in 5 per cent glucose lose their activity within 48 hours even when kept in the cold; moreover when administered they are rapidly excreted. The authors found that in olive oil the drug could be kept for 10 days in a refrigerator and still be active and also that by being suspended in oil it remained longer in the body.

In practice 100 000 Oxford units are shaken for 10-15 minutes in 10 cc. of the oil previously sterilized in an autoclave. Four cases of yaws are recorded in which about 15 000 units were injected intramuscularly each day for 7 days a total of a little over 100 000 units. By the third day the lesions had cleared or were fast disappearing and by the end of a week clinical cure was complete but serologically the Meinicke and Vernes reactions remained unchanged or were slightly reduced and continued so during subsequent periods of observation [but these were short: two months in two patients and only one month in the other two].

LEPROSY

IBARRA PÉREZ R. & GONZÁLEZ PRENDES M. A. Incidencia de la lepra en Cuba según la raza. [Racial Incidence of Leprosy in Cuba.] *Rev. Sifilografía, Leprología y Dermatología*. Marianao, Cuba. 1946 v 3 No 1 19-24 [11 refs.]

[It is difficult to reconcile the statements in the letterpress of this article with the figures presented in their support.] The authors claim at the outset that Cuba differs from other Latin American countries in that there is no half-caste population from crossing of the Spanish blood with that of the original indigenous inhabitants because the latter were exterminated in the 16th century. Nevertheless the percentage of half-castes from admixture of white and negro bloods is high. Whites number 3 553,312 (74.4 per cent. of the whole), negroes 463,226 (9.7), half-castes 743,115 (15.5) and Chinese 18,929 (0.4 per cent.). The lepers among these number respectively whites 1,649 (4.6 per 10 000), negroes 340 (7.3), half-castes 408 (5.4) and Chinese 30 (15). In the face of

these figures [the totals only are given not the incidence by population] the authors claim that "race is not a predisposing factor because the incidence is the same among the different races composing the population." The slight increase among the black and yellow races is due, they say to economic and hygienic conditions—the people living in poor ill-fitted dwellings devoid of sanitation and overcrowded they are badly fed and predisposed to disease by the presence of malaria syphilis tuberculosis and parasitic infection. The authors next proceed to estimate the incidence exclusive of Oriente Province in which the population is given as 1,362,489 and they show that among the whites there are 1,313 cases [4.8 per 10,000] among the negroes 181 [6.0] among half-castes 236 [6.1] and among Chinese 28 [17.4]. They conclude from this that "the slight increase in the non-white races is due to the causes mentioned above." Lastly they give analogous statements on Oriente itself 337 lepers among 835,360 whites [4.0 per 10,000] 159 among 161,712 negroes [9.9] 172 among 356,532 half-castes [4.8] and 2 among 2,835 Chinese [6.9].

Commenting on these figures the authors state "The increased percentage of negro lepers occurs exclusively at the cost of the diminution in the white population. The half-castes and the Chinese retain the same percentage incidence." [It will be seen that the figures do not bear this out. In the Tables given the totals and the percentages of the whole are stated, not the morbidity by race. The figures given (by the abstractor) in square brackets have been calculated on the total figures in the text.]

H. Harold Scott.

TRESPALACIOS F. & GONZÁLEZ PRENDES M. A. Primeros síntomas y edad probable de contagio en lepra. Estudio de 315 casos asilados en el Hospital San Lázaro de la Habana. [Earliest Symptoms and Probable Age of Infection in Leprosy. *Rev. Sifilografía, Leprología y Dermatología* Marianao Cuba 1946 Jan. v 3 No 1 38-48.]

This record is based on a study of 315 patients in the San Lázaro Hospital, Havana. 233 were males 82 were females. 200 were whites 46 were negroes 50 were half-castes and 19 were Chinese. 262 were Cuban born 53 were from abroad.

Sometimes the first symptoms appeared suddenly (after months or even years of incubation) as for example a rhinitis with epistaxis at other times and more commonly insidiously with maculae or some cutaneous manifestation—erythema pigmentation or an achromic patch. In a Table giving the first symptoms it will be seen that 60 started with erythematous maculae, 25 with infiltration of the ears, 23 with patches of anaesthesia 17 with pigmented maculae the same number with systemic symptoms such as headache fever lassitude etc. ROGERS and MUIR, in an analysis of 252 cases found achromic maculae and anaesthetic patches as the first symptom in 188 or 74.7 per cent. In 206 patients (63 per cent) the symptoms appeared first before the age of 25 years 37 within the first 10 years of life the largest number in any single year was 28 in the 20th. The probable age when infection was contracted is also given in quinquennia the figures up to age 50 years being 3 31 60 68 45 30 20 20 9 and 13. [In another table six are said to have contracted the disease "soon after birth, in the first year of life."] The average age of contagion worked out at 18 years and the appearance of symptoms at 23 years. Of the total, 253 (80.3 per cent) suffered from the lepromatous form 49 (15.5 per cent) from a "non-characteristic or non-specific type" and 9 from the tuberculoid type [these total 311 not 315. During 1945 there were 31 deaths at the hospital 15 patients escaped, four were released on parole and there were 16 re-admissions.]

JAUQUET DEL POZO G. La ginecomastia en la lepra. [Gynaecomastia in Leprosy] *Revista "Fontilles"* Valencia. 1946 Jan. No 4 283-95 4 figs. on 1 pl. [29 refs.]

RODRIGUEZ PASCUAL, C. Alteraciones nasales en la lepra. [Nasal Changes in Leprosy] *Revista Fontilles* Valencia. 1946 Jan. No 4 297-303 8 figs on 2 pls. [19 refs.]

DUEÑAS C & ABAD R. Serologia de la lepra. [Serum Reactions in Leprosy] *Revista Fontilles* Valencia. 1946 Jan No 4 307-18 1 fig [28 refs.]

Three tests carried out with the serum of lepers are recorded. Either's complement fixation, Rubino's test with sheep's cells and Muchow and Levy's flocculation with leproma extract.

Sera from 249 patients with various types of leprosy were tested and the results are summarized thus —

International Classification	Number of Patients	Reac- Ertner — Posi- tives	Per cent.	R. Rubino — Posi- tives	Per cent	R. Muchow — Posi- tives	Per cent
L1	2	—	—	1	50	2	100
L2	43	13	30.2	28	65.1	35	81.3
L3	61	19	31.1	42	68.8	51	83.6
N1	6	—	—	1	16.6	1	16.6
N2	18	5	27.7	13	72.2	13	72.2
N3	52	10	19.2	39	75	38	73
L2 N2	20	10	50	15	75	19	95
L3 N3	15	7	46.6	8	53.3	13	86.6
L3 N2	6	3	50	6	100	6	100
L3 N3	28	14	53.8	22	84.6	24	92.3
Total	249	81	32.5	175	70.2	202	81.1

With the Muchow and Levy test 81.1 per cent of the specimens were positive in some degree. The percentage distribution of positive results according to intensity of reaction is shown in the following table —

	+	++	+++	++++
L1	—	100	—	—
L2	18.2	32.2	23.2	11.8
L3	16.3	32.7	24.5	9.8
N1	16.6	—	—	—
N2	16.6	22.2	27.7	5.5
N3	5.7	25.0	30.7	11.5
L2 N2	10.0	30.0	45.0	10.0
L2 N3	—	20.0	47.3	20.0
L3 N2	—	—	33.3	66.6
L3 N3	—	7.6	45.3	38.4
Total per cent	10.4	25.3	30.5	14.8

These same sera were tested also for syphilitic and tuberculous reactions. For the former the Wassermann Hecht M.R.R. II Kahn Leisboff and Hinton (1933)

for the latter the Bestredka Daranyi and the Matefi. The authors conclude that among those of the same clinical type of leprosy the number and intensity of the reactions depend on the length and severity of the disease and that when the results of the leper sera coincide with those of the syphilitic tests both being positive there is probably a dual infection of leprosy and syphilis.

H Harold Scott.

GUILLEN PRATS J & GOMEZ LUCAS R. Penicilina y lepra. [Penicillin in Leprosy *Revista Fontilles* Valencia. 1946 Jan. No. 4 305-6.

The sodium salt of penicillin has been tried in a severe case of leprosy L_2 with, so far good effect. The patient was a man of 43 years who had suffered from the disease for 16 years. His nose and ears were much enlarged by numerous lepromata eyebrows gone interstitial keratitis in both eyes especially the left, lepromata of shoulders thighs and hands many confluent oedema and infiltration of legs and feet. Bacilli were present in the nasal mucus and in the skin lesions. Red cell sedimentation 65 mm in one hour 110 in two hours. The penicillin was injected intramuscularly 10 000 Oxford units every three hours. Early injections caused febrile reactions disappearing in 24 hours there was much local pain. By the third day the patient stated that he felt better and the vascularization of the conjunctiva and cornea was less. After 300 000 units the oedema of the feet and legs was reduced the lepromata of the shoulders were smaller he was much more cheerful and no longer suffered from insomnia. For 12 days the drug could not be obtained and the treatment had to be suspended. It was then resumed till he had had two million units. With this new series the early injections caused even greater febrile reaction than had the first but this reaction ceased in 36 hours and was never serious enough to call for suspension of the treatment. By this time the lepromata were reduced, oedema of the feet and legs was no longer observed, eye lesions were less marked and the euphoria continued as the patient was convinced of the improvement. The blood sedimentation rate was now 42 and 81 in one and two hours respectively. The amelioration had continued for 1½ months at the time of report. The authors acknowledge that this interval is short and think that higher doses should be given before the final assessment of the value of penicillin is made but so far they are favourably impressed by its action in leprosy.

HELMINTHIASIS.

GAMA, C. & DE SA J M. Esquistosomose medular (Granulomas produzidos por ovos de esquistosoma Manson (Schistosoma Manson) comprimindo a medula epicono cone e cauda equina—Paraplegia flácida) [Schistosomiasis of the Spinal Cord. Granuloma due to Ova of *Schistosoma manson* pressing on the Lower Spinal Cord.] in *Facul de Med. Bahia* 1944-45 v 4 187-231 6 figs. [234 refs.]

Spinal symptoms have been recorded more than once in patients infested with *Schistosoma* but rarely has the cause been proved to be the helminth or its ova. DAY and KENAWY recorded a case in 1896 [see this *Bulletin* 1896

v 33 951] in which *S. haematobium* was the agent and there is another by HOFF and SHABY in 1939 [this *Bulletin* 1940 v 37 147] in which intestinal lesions were present and ova of *S. haematobium* found in the urine. In the latter case ova were not found in the spinal cord and all that can be said is that 'myelitis with mental disturbance occurred in a patient infested with *S. haematobium*'.

S. japonicum ova have also been found in the human brain [noted in BUNKE and FORSTER's *Handbuch der Neurologie*].

The case here recorded is that of a man aged 42 years with signs of flaccid paraplegia. His father had died of tuberculosis and several relations had had cancer. The paraplegia came on when he was in good general health and comparatively rapidly with pain in the loins and legs, formation retention of urine and faeces and loss of patellar abdominal cremasteric and plantar reflexes. The blood showed an eosinophilia of 16.3 per cent. [no details as regards totals of leucocytes are given and the percentage as stated adds up to 119.4]. Radiological examination after injection of lipiodol indicated obstruction beginning at the 6th dorsal vertebra and extending to the 12th where it became complete. A little later complete blockage of the spinal canal was found to be at the level of the 2nd lumbar vertebra.

Operation was decided upon and a swelling was found at this level. It was thought at first to be cystic but puncture did not draw off any fluid. A portion was taken for section and the tumour removed. It was found to consist of five small nodules in the centre of each of which was a foreign body which proved to be an ovum of *S. mansoni*. The patient was treated with foudrin stibosan stibeny] antimonialine and when these could not be obtained, with tartar emetic in 1 per cent solution and deep radiotherapy. There was good improvement within three weeks voluntary movements were returning in the toes and leg muscles and even before this he was regaining control of the bladder.

The actual source of infestation was not determined with certainty. The patient had bathed in waters in which the intermediate host *Australorbis glabratus* or *Planorbis olivaceus* was known to be present in 1926 and in 1941 1943 and 1944 and after the first at all events he had suffered from severe intestinal disturbance and frequent attacks of diarrhoea.

H. Harold Scott

GONZALEZ RINCONES P. Stibioterapia per os [Antimonial Medication by Mouth.] *Gac Med de Caracas* 1945 Sept. 15 v 53 No 17 127-41 11 figs. & 2 charts.

There are obstacles to administering tartar emetic by mouth because the gastric juice breaks it down since the HCl is stronger than the tartaric acid of the antimony potassium tartrate and more toxic compounds are formed. On the other hand there are drawbacks to intravenous administration. The salts are changed by heat and are difficult to sterilize in children and in some women the vein is not always easy to find, the patient has to attend at the doctor's surgery and this he often fails to do regularly.

The author has therefore aimed at finding some way of administering the drug by mouth without causing intolerance or signs of antimony poisoning. He has had pastilles made combining the drug with atropine 1/20 mgm. to every cgm. of the tartar emetic to counteract its stimulant effect on the vagus and adding a small proportion of vitamin B₁ (thiamin) and coating the whole with keratin to allow it to pass undecomposed into the intestine. He has used these for treatment of infestations by *Schistosoma mansoni* observing by X-ray the passage of the pastilles until they are dissolved and absorbed in the large intestine. Two cases are quoted and X-ray photographs are reproduced showing the progress of the pastilles. He gave four tablets (or pastilles)

the first day two doses of two each 8 on the second, 8 on the third 10 on the fourth (all colic and tenesmus had disappeared by this time) 12 on the fifth, and so on. By the 10th day 120 pastilles had been taken and, in all, 1.2 gm. of the drug. All clinical signs had cleared. Slight gingivitis with stomorrhoea and a metallic taste indicated that the drug had been absorbed. The maximum dose in a day should be 2 cgm. per 10 kilos given in two or three doses in the 24 hours

JANSEN G. Experiências sobre a profilaxia da esquistosomose mansoni no estado de Pernambuco. [Nota prévia. Prophylaxis of *Schistosoma mansoni* Infection in the State of Pernambuco. Preliminary Note.] *Brasil Medico* 1946 Mar 18 & 25 v 60 Nos. 20-21 177-9 3 figs.

This account deals with the Catende Municipality where was installed the first centre for combating schistosomiasis in Brazil.

Preliminary examination of the faeces of 6,539 persons showed that 3,482 (52 per cent) were positive. For initial experiment 50 patients were subjected to stibin intramuscularly and a like number to each of antimonyl, stibetine and 1 per cent. tartar emetic all administered intravenously. The numbers cured were respectively 11 28 37 and 49 cure implying three consecutively negative examinations.

Treatment was now started in earnest and up to December 1945 [the date of beginning the work is nowhere stated] of 1,348 receiving tartar emetic 1,159 (86 per cent) were cured of 292 receiving stibetine intramuscularly 42 (14.3) of 169 receiving it intravenously 97 (56.8) of 12 receiving antimonyl intramuscularly 5 were cured of 117 intravenously 39 (33.3) of 50 receiving stibin intramuscularly 11 (22 per cent.) Altogether of 1,868 patients treated 1,353 (68 per cent) were cured. No details of the composition of these drugs are given.

Tanks for washing clothes and public baths were installed and also house latrines for of 1,252 registered houses 424 had no sanitary installations of any kind.

Examination of the vector *Australorbis centricornis* in various waters was carried out in July 1943 and again in December 1945. In 1943 of 732 from the Rio Piranga 10 were positive of 607 from the Rio Panelas 16 (or 1.32 and 2.63 per cent. respectively) in 1945 the numbers examined were 64 and 90 and the numbers positive 0 and 2 respectively lime having been applied in the interval.

BERBERIAN D. A. Treatment of *Hymenolepis nana* Infection with "Acranil." *Amer J Trop Med* 1946 May & 26 No. 3 339-43 [15 refs]

25 cases of *Hymenolepis nana* infection in children were treated by a synthetic acridine derivative Acranil. The night before the administration of Acranil the children were each given 0.1-0.2 gm. Calomel as aperient. The following morning Acranil was given on an empty stomach in 0.1-0.5 gram doses according to age. Three hours later a saline purge was administered. Treatment with Acranil was continued in smaller doses for three more days without any further purgation. 23 out of 25 children treated by this method remained free of worms for 14 days

BROWN H. W. The Use of Gentian Violet in Children Infected with *Ascaris lumbricoides*. Reprinted from *J Pediatrics* 1946 Feb & 28 No 2 160-64 [14 refs.]

"1 Gentian violet therapy for ten consecutive days did not produce findings suggestive of migration of *A. lumbricoides* or of intestinal or pharyngeal obstruction in twenty treated children. It appears therefore that gentian violet is not a specific irritant to *Ascaris*

2. A 37 per cent. reduction in the *Ascaris* egg count following gentian violet therapy suggests that this substance is slightly effective against *Ascaris*

BROWN T. McP. STIFLER, W. C. Jr & BETHEA, W. R. Jr Early Filariasis. *Bull. Johns Hopkins Hosp* 1946 Mar & 78 No 3 126-54 9 charts. [31 refs.]

This paper deals with the early clinical manifestations of filariasis as determined by the study of three groups of American servicemen—two of these groups served in the South Pacific islands (Tonga tabu and Woodlark) and the third, a control group had served in New Guinea, where manifestations of filariasis in American troops have been slight or had had no tropical service. These same cases have already been the subject of extensive reports by HODGE, DEMHOFF and VANDER VEER [this *Bulletin* 1945 & 42 1020] and by BEHM and HAYMAN [this *Bulletin* 1946 & 43 762]. The present account does not materially add to the information already published and should be consulted in the original in conjunction with the other papers by those interested.

KUUTUMEN EKBAUM E. Phenothiazine in the Treatment of Enterobiasis (II) *Canadian J. Pub Health* 1946 Mar v. 37 No 3 103-13. [22 refs.]

Phenothiazine was given to 1,275 subjects (900 children and 375 adults) infested with *Enterobius vermicularis* and the results of this treatment were estimated by means of the N.I.H. swab. Before and after the treatment the blood haemoglobin of 25 children and 9 adults was estimated.

The ages of the subjects who came from all social levels ranged from three months to 78 years. Eleven children were less than 1 year old and 8 adults were 60 years old or older. Those under 15 years old are called children those over 15 years are called adults. Before treatment NIH swabs were taken on five consecutive mornings if eggs of *E. vermicularis* were found, treatment was given. During the second week after the end of treatment, 7 NIH swabs were taken on five consecutive mornings. When the first course of treatment was not effective treatment was repeated four weeks later. Diagnostic swabs were taken from 2,505 subjects (1,350 children and 1,125 adults) and phenothiazine was given to 1,275 (900 children and 375 adults). Post treatment swabs were taken from 790 (534 children and 206 adults) and the results given are based on these.

The phenothiazine used was supplied by the Connaught Laboratories and was refined and made into 0.5 gm tablets by SIEBENMANN [see SCHMITZER, SIEBENMANN and BETT this *Bulletin* 1942 v. 39 882]. The author emphasizes the necessity of using highly purified phenothiazine.

Two dosage scales were tried. Scale A was 2.5 to 9 gm. for children in proportion to their age and 9 gm. for adults given over four to six days. This scale caused toxic reactions especially in small children and it was abandoned. Scale B was therefore used, and was given over a period of 4 days. This scale was as follows—

Under 2 years	0.25 gm.	per day	total 1 gm.
2 to 3 years	0.5 gm.		2 gm.
4 to 5 years	0.75 gm.		3 gm.
6 to 7 years	1.0 gm.		4 gm.
8 to 9 years	1.25 gm.		5 gm.
10 to 11 years	1.5 gm.		6 gm.
12 to adult or over 15 years	1.75 gm.		7 gm.

For small children the tablets were crushed and mixed with food or orange juice. Other subjects were advised to chew and swallow the tablets. Extra fluid and avoidance of constipation were advised during treatment. Tables show the results of treatment.

Dosage scale B was given to 584 persons (408 children aged 7 months to 15 years and 176 adults over 15 years). The swabs of 327 (80.2 per cent.) of the 408 children were negative after the first course of treatment those of 76 children (18.6 per cent.) after the second course and 5 (1.2 per cent.) children needed a third course. Of the 176 adults 150 (85.2 per cent.) gave negative swabs after the first course 20 (11.4 per cent.) gave them after a second course and 6 (3.4 per cent.) needed a third course.

The toxic reactions are discussed in detail under the following headings —

Anaemia —Reduction of the haemoglobin level was the commonest evidence of this and was sometimes so severe that emergency treatment was required. The case histories of three girls aged 18 months 8 years and 2 years respectively are given to illustrate this form of toxic reaction. Blood transfusions were given successfully to all three. The haemoglobin values of 25 children and 9 adults were estimated all were given the dosage scale B the first estimation being done before the first dose and the second on the fifth day after the last dose. The results showed that two children had a decrease of 3 gm. per 100 cc. of blood four a decrease of less than 2 gm. 13 a decrease of less than 1 gm. while two showed no change and two showed slight increase. Of the nine adults tested two showed a decrease of more than 2 gm. one a decrease of 1 to 2 gm. four a decrease of less than 1 gm. and two showed no change. The author refers to the work of MILLER and ALLEN [this *Bulletin* 1942 v 39 781] and of BERCOVITZ *et al* [this *Bulletin* 1943 v 40 929] who also found anaemia after administration of phenothiazine.

Skin Reactions —These were neither serious nor common. They included skin rashes pruritus and oedema.

Fever —Other authors have reported a rise of temperature during treatment with phenothiazine. The present author reports a temperature of 100°F in a girl aged 6 years after one dose of phenothiazine and a temperature of 102°F in an adult female after one dose of 1.75 gm. treatment of both these subjects was discontinued.

Miscellaneous reactions were slight pain in the abdomen in two children several mothers reported pallor and decline of appetite during treatment of children. The author points out that various workers have used very variable doses of phenothiazine and he claims that all the serious toxic reactions reported in the literature have occurred after doses above his dosage scale B although sometimes large doses have had no ill effect. Thus MANSON BARR [this *Bulletin* 1941 v 38 516] gave 7 to 40 gm. and ELLIOTT [this *Bulletin* 1943 v 40 702] gave 24 gm. Both these authors however gave a laxative with the phenothiazine and may thus have avoided toxic reactions. Some of the toxic reactions experienced by the present author were he thinks related to previous ill health and it would have been wiser to have reduced the dose and to have repeated it if necessary or to have waited until the health improved. [It would appear wise to raise the haemoglobin level especially before phenothiazine is given.]

Discussing precautions that should be taken the author says that phenothiazine is more toxic than gentian violet but is more effective and is apparently tolerated by a larger number of individuals than gentian violet. It also requires a shorter period of treatment and is easily given to small children who cannot swallow gentian violet tablets. The phenothiazine must be highly purified the patient should be in fair general health constipation during treatment should be avoided, the drug should be discontinued at once if toxic reactions appear and it should not be repeated before 3 to 4 weeks after the first course. Pregnancy and lactation seem to be no bar to its use but supervision of such patients is necessary. Discussing the treatment of families with phenothiazine

It is possible that thiamin lack is the one aetiological factor which accounts for both these diseases. At first it seemed a typical outbreak of beriberi, although the explosive character suggested that it might be epidemic dropsy.

PROC. ROY. SOC. MED. 1946 May v 39 No 7 357-60 (Sect. of Med. 9-12)
 Discussion Nutritional Neuropathy in Repatriated Prisoners of War from the Far East. CLARKE C. A. & SNEDDON I. B. COLLINAN E. R. SPILLANE J. D. KIRMAN B. D.]

Drs Clarke and Sneddon reported some of the neurological signs found in men who had been released from Hong Kong [see *Bulletin of Hygiene* 1946 v 21 527]. Some patients developed fresh neurological signs in hospital while eating a full diet supplemented by adequate amounts of thiamin parenterally. This fact was part of the evidence put forward by them in support of the theory that the neuropathy was not caused by simple lack of the vitamin B complex. In their opinion the syndrome was due to an anti-vitamin or toxic factor present in the rice that inactivated what little thiamin was present in the diet. The thiamin deficiency was rendered more severe by the low protein intake that prevented adequate synthesis by bacteria in the gut. Changes in the nervous system appeared to be irreversible.

Dr Collinan described an outbreak of beriberi amongst East African troops whose diet consisted largely of lightly milled rice which in its uncooked state contained theoretically adequate amounts of thiamin. It was found that the rice which was old and showed surface contamination with a variety of moulds lost over 70 per cent of its thiamin during cooking whereas similar freshly milled rice lost only 30 per cent. [See also COLLINAN *et al.* above.]

Dr Spillane summarized the clinical features of the nutritional neuropathic syndromes he had observed in prisoners of war during the past few years.

Dr Kirman reported that there was no increase in the incidence of psychosis amongst released prisoners who passed through India and none of the few psychotics seen showed signs of pellagra.

H. E. Harding

SIMPSON J. "Burning Feet" in British Prisoners-of-War in the Far East. *Lancet* 1946 June 29 950-61

Large bodies of Allied troops in Java capitulated to the Japanese in March 1942. Signs of deficiency disease which soon affected half of the prisoners developed after four months showing first as lesions of the mouth and scrotum. Shortly after these signs of pellagra and ariboflavinosis had become manifest on a large scale a few men began to report sick with "burning feet" and during the following 3 months 10-12 per cent. of the prisoners had this complaint.

Most of the sufferers showed exaggerated knee and ankle jerks but no ankle clonus nor extensor plantar response and no spasticity. Early hyperaesthesia in the feet and lower legs was usually replaced by hyposaesthesia, both sensory alterations showed a patchy distribution. No ataxia, incoordination or loss of joint sense was demonstrated. The condition commonly became so severe as to dominate the life of the sufferers. Treatment with vitamin A ($\frac{1}{4}$ oz. red palm oil daily for 4-6 weeks) produced no improvement. 10 patients given 10 mgm. thiamin daily for a month showed no benefit. Giving the kacang hijau bean (*Phaseolus radiata*) in doses of 150 gm. daily cured the syndrome in 4-6 weeks. This bean is reported to be a rich source of vitamins B₁ and B₂. In other camps the syndrome was cured by yeast or marmite.

Associated with burning feet but appearing a little later, local eye irritation developed, followed closely by blurring of the vision and loss of visual acuity. After a rapid onset the visual upset usually remained stationary or tended to

improve very slowly About 10 per cent of those with burning feet developed retrobulbar neuritis visual defects occasionally developed without the peripheral pains but the two conditions were usually associated. Cure of the burning feet syndrome did not affect the visual condition

H E Harding

HARRISON G F Nutritional Deficiency, Painful Feet, High Blood-Pressure in Hong-Kong *Lancet* 1946 June 29 961-4 1 fig

Although many other conditions were met with in prisoners-of-war in Hong Kong the outstanding symptom almost throughout the Japanese occupation was painful feet In the early days the pain was so severe that the only drug that gave relief was morphine in $\frac{1}{2}$ grain doses by mouth. Later the intensity of the pain diminished and less potent drugs were effective The pains were accompanied by lost or diminished sensitivity to touch pin prick heat and cold and often by loss of joint sense and sense of position in the toes.

Eleven patients were given 10 ml. of 10 per cent calcium gluconate intravenously on several occasions. They appreciated a flush spreading down the body and if this sense of warmth reached the feet the pain was sometimes relieved for a time Some of the patients who were given 20 mgm. nicotinic acid subcutaneously or 100 mgm by mouth obtained relief from pain and one patient experienced almost immediate complete relief for about 5 minutes after inhaling the contents of one ampoule of amyl nitrite Exercise had a beneficial effect on the pain and those who conscientiously walked as much as possible each day made a speedier recovery than those who could not or would not make the effort Recovery took years rather than months despite daily doses of 20 mgm. nicotinic acid subcutaneously 3-5 mgm. thiamin chloride by mouth, yeast drinks and other foods containing vitamin B complex [Much of this is contrary to the findings of Simpson—see above.]

At least 19 per cent. of the 400 patients suffering from malnutrition had at some time—usually at an early stage—a high diastolic blood pressure. In many of these the systolic pressure was also raised. In a few patients simultaneous records were made each week of the blood pressure in arm and leg Almost always the systolic pressure was higher in the leg than in the arm and in one instance was 50 mm. Hg higher Not all patients with a raised blood pressure had pain.

The author suggests that the cause of the pain and of the high diastolic pressure was spasm of the blood vessels in the legs.

H E Harding

BLANKENHORN M A, VILTER, C. F, SCHEINKER I M & AUSTIN R. S Occidental Beriberi Heart Disease *J Amer Med Ass* 1946 June 29 v 131 No 9 717-26 1 fig [Refs in footnotes.]

Heart disease as a manifestation of beriberi was recognized in 12 patients admitted to the Cincinnati General Hospital from 1940 to 1945 All the patients were chronic addicts to alcohol but this substance is not considered to be a direct cause of the condition. The ages of the patients ranged from 33 to 67 years and only one was a woman. Five patients died in hospital and one died 3 months after being discharged. Two patients recovered with rest in bed, a full diet and digitalis one of these died 3 months later The response to large doses of thiamin was rapid in only one patient the others recovered slowly

The authors think that the criteria for diagnosis of the condition have been set too high, and propose the following as aids to its recognition (1) insufficient evidence of other aetiology (2) a diet deficient in thiamin for at least three months (3) signs of neuritis or of pellagra (4) enlargement of the heart with sinus rhythm (5) dependent oedema (6) a raised venous blood pressure

Percentage absorption figures were calculated directly from the difference between the amount of fat ingested and that found in the faeces over the comparable period. When the percentage absorption is calculated in this manner it was found to be 95 or over in the controls. In practice it was found that cases with percentage absorption of less than 85 invariably showed associated signs and symptoms confirming a fat-absorption defect.

Seventy to eighty per cent. of faecal fat is normally present as fatty acid or soap. The degree of splitting of neutral fat is interpreted as an index of pancreatic function but this is not invariably so because even after complete pancreatectomy in man lipolysis still occurs for lipase exists in the gastric and intestinal juices. The percentage hydrolysis of fat in the faeces cannot therefore be regarded as a reliable index of normal pancreatic function.

The interpretation of changes in the chemical characteristics of faecal fat is at present unsatisfactory. The authors were unable to demonstrate any constant features in the faecal fat in their series. Usually about half the split fat is present as soap although considerable variations are found in case to case.

It has been suggested that the rapid rate of passage of intestinal contents through the alimentary tract might constitute an important factor in the production of a fault in fat absorption. In those cases of diarrhoea in which charcoal passed through the alimentary tract within seven hours of ingestion, fat absorption was normal. It is therefore concluded that when intestinal hurry can be demonstrated in these cases the colon is primarily involved and consequently defective absorption of fat cannot be attributed to lack of time.

In addition to the investigation of the amount of fat in the faeces the absorption of fat may also be investigated by examination of the blood during the post absorption period either by chemical analysis or by chylomicrograph. In the normal subject a characteristic lipaemia can be demonstrated in the systemic blood during four hours after ingestion of fat and it was a striking feature of many of the cases of defective fat absorption that whilst fat balance tests indicated that 70-80 per cent. absorption had occurred, there was little or no change in the blood-fat.

The constantly flat chylomicrograph curve and correspondingly low value for blood fat obtained in chemical analysis are difficult to explain, unless it is assumed that the fat is leaving the intestine by some pathway other than the thoracic duct and systemic blood.

P. MANSION BARR

KARAMCHANDANI P. V. & HYDER G. Analysis of 242 Cases of Sprue in Indian Troops. *Indian Med Gaz.* 1946 Jan. v 81 No. 1 11-13

"Para sprue" corresponds to what has so far been known as "incomplete sprue" "chronic jejuno-ileal insufficiency" or a vitamin B deficiency syndrome allied to sprue.

The authors view of the pathological process is as follows.—With faulty intake and faulty absorption the stress initially falls on the delicate columnar intestinal epithelium and the symptoms evoked depend upon the site and extent of the damage. When the duodeno-jejunal region is attacked, there may be deficiency of bile flow, failure of emulsification, and increase of split fat in the stools because it cannot be absorbed, or there may be deficiency of pancreatic secretion resulting in high total fat content in the stools. When the ileum is affected, the fat content in the stools is normal, and the diarrhoea is of the irritative type (enteritis) but when the colon is involved blood and mucus may appear in the evacuations.

The post-mortem appearances in two typical cases are recorded. The small intestine is described as wasted, with destruction of villi and desquamation of the epithelium.

A series of 242 cases of the sprue syndrome was observed during a period of 2½ years. These were grouped as follows—dyspepsia and diarrhoea 88 dyspepsia diarrhoea and glossitis 96 the same signs with addition of anaemia 54 the same with excessive split fat in the stools 4

The majority of cases fell within the age-group 20-25 the duration of the disease bore no relation to its severity Thirty-one cases had associated amoebic infection but six only had blood and mucus in the stools

Treatment at first consisted of 8 oz. of milk given every 2 hours from 6 a.m. to 10 p.m. This was increased to 10 oz during the next 4 days. This diet provided a Calorie value of 1 625 with 82 gm protein 90 gm. fat and 120 gm. carbohydrate During the second and third weeks additions were made to the diet which was increased to 2 560 Calories with 97.70 and 458 gm of protein fat and carbohydrate respectively During the next three weeks it was augmented to 3,200 Calories with 154.114 and 596 gm. protein fat and carbohydrate respectively Vitamin-containing foods fruit juices and liver preparation were given

Those with concomitant amoebic infection were given routine treatment by emetine Yatren emetine bismuth iodide and Amoebiarson

Of the 242 cases 129 were cured and discharged to duty 22 were improved and placed permanently in category C 67 were improved placed in category C but relapsed 22 were not improved and were invalided out of the service. Two patients died.

P Manson Bahr

SPIES T D FROMMEYER W B GARCIA LOPEZ G LOPEZ TOCA R. & GWINNER, Georgia Haemopoietic Action of 5-Methyl Uracil (Thymine) in Tropical Sprue *Lancet*. 1946 June 15 883-5 2 figs.

Since synthetic 5-methyl uracil (thymine) produces a striking haematological response in Addisonian pernicious anaemia in relapse and as the bone marrow of this condition is indistinguishable from that associated with the macrocytic anaemia of tropical sprue four patients suffering from relapse of the latter disease were given 7.5 gm. of the drug twice daily by mouth for 9 to 16 days. In each case there was a definite haematological response parallel to although less dramatic than that which follows the administration of synthetic folic acid. Reticulocytosis began on the fourth or fifth day reaching a peak on the eighth or ninth day of treatment and was followed by an increase in the erythrocytes and haemoglobin On the day after the peak reticulocytosis the bone marrow consisted largely of normoblasts with almost complete obliteration of the megaloblastic arrest found before treatment Clinical improvement was manifested by an increase in appetite and strength resolution of the glossitis and disappearance of the burning and soreness of the tongue and mouth. Although the stools did not become fully formed, they showed as early as the fourth day of treatment in one case a return towards normal. X-ray examination of the gastro-intestinal tract showed a substantial decrease in intestinal motility in spasm and dilatation and in the amount of puddling of barium after administration of the drug Glucose tolerance tests indicated that intestinal absorption improved after therapy

DARBY W J & JONES E Treatment of Sprue with Synthetic *L. casei* Factor (Folic Acid, Vitamin M) *Proc Soc Exper Biol & Med* 1945 Nov v 60 No 2, 259-60

This is a report of the first two of the three cases of sprue treated with synthetic *L. casei* factor which were recorded by DARBY JONES and JOHNSON (cont)

[the *Bulletin* 1946 v 43 667 the authors state that "there appears to have been published no previous experiences with this factor in the treatment of sprue"
J F Corson.

CARRUTHERS L B Chronic Diarrhoea treated with Folic Acid. *Lancet* 1946 June 8 849-50

Four severe cases of hypochromic anaemia were treated with 40 to 60 mgm. folic acid daily for five to seven days without any noteworthy improvement in the anaemia but in two of the patients who had chronic diarrhoea an immediate and definite improvement in the stools occurred. This led the author to try the effect of folic acid on six other cases of chronic diarrhoea of vaguely determined aetiology. In these cases the stools became normal, or approximately so within two to five days of starting the treatment. He therefore suggests that in any long standing diarrhoea a nutritional factor prolongs the production of abnormal stools and that folic acid appears to correct this defect.

HAEMATOLOGY

ZUELLER W W & OGDEN Faith N Megaloblastic Anemia in Infancy A Common Syndrome responding specifically to Folic Acid Therapy *Amer J Dis. Children* 1946 Mar v 71 No 3 211-43 7 figs. (1 coloured on 1 pl.) [Refs. in footnotes.

Macrocytic anaemia commonly occurs in infancy as a result of a specific dysplasia and dysfunction of the bone marrow developing in the absence of an essential haematopoietic principle. Clinically the outstanding feature is extreme pallor with weakness loss of appetite and irritability fever vomiting and diarrhoea are common complaints. In the series of the 23 patients studied, many of the infants had cough, convuls or both for several weeks before admission to hospital and the beginning of the illness was usually referred to the onset of these symptoms. In several cases petechiae had been noted by the parents. On examination, a soft systolic murmur could often be heard over the praecordium, and slight cardiac enlargement was evident. The liver was invariably increased in size but the spleen was palpable in only 10 of the patient. In no case was there any appreciable lymphadenopathy. Half the patient were underweight six had clinical signs of scurvy and 19 had fever of variable degree.

The disturbance in erythropoiesis was shown in the bone marrow by the prevalence of young basophilic and polychromatic cells limitation of mitotic activity abnormal karyokinesis an abnormal nuclear structure lobulation and distortion of the shape of the nuclei an increased tendency to demarcation, and an increase in the size of the cells and in the relative amount of cytoplasm at all levels of maturation. The pattern corresponded basically to that seen in pernicious anaemia in relapse and was typical of alterations produced by lack of a so-called maturation factor resulting in multiplication of cells confined mainly to primitive levels. Similarly leucopoiesis showed constant qualitative changes leading to a relative decrease in the number of mature cells.

The peripheral blood showed always a severe anaemia with haemoglobin levels near 5 gm. per 100 cc. and often below 3 gm. Reduction of the red blood cells was often even more pronounced, and the colour index was usually, but not invariably, well above unity. The mature erythrocytes appeared well filled with haemoglobin and this was borne out by the mean corpuscular haemoglobin concentration. Polychromasia and punctate basophilia were invariably present to a slight degree and Howell Jolly bodies and Cabot rings were often seen. The percentage of reticulocytes was usually small and obviously did not account for the macrocytosis of the blood. Nucleated red cells were always found but sometimes only after prolonged search. The white cell count was below 10 000 per cmm in most cases despite the presence of fever or other signs pointing to infection and in some cases a frank leucopenia existed. Neutropenia was common being as a rule moderate but sometimes pronounced. The neutrophils were usually much larger than normal being of two basic types with transitions between the extremes. The first was characterized by excessively large nuclei of the metamyelocyte type often showing budding, twisting and the beginning of segmentation while the granulation of the cytoplasm was uneven and suggested immaturity. The second type showed fully developed granulations of the cytoplasm and excessive segmentation of the nuclei with long tenuous filaments connecting the lobules. The platelets were reduced in number often markedly and the thrombocytopenia accounted for the prolonged bleeding time, inadequate clot retraction and the haemorrhagic manifestations shown by several of the patients.

Infections and other complications were common and multiple transfusions were often necessary. These factors limited the number of cases suitable for the evaluation of specific therapy to 12. In these latter the effect of crude or purified liver extract given parenterally and that of folic acid, appeared to be identical whether the folic acid was given orally or parenterally, in the form of concentrates or as synthetic material. A second reticulocyte response could not be produced by liver extract when folic acid had been given first and *vice versa*. Since liver contains folic acid the identity of the therapeutic effect raises the question whether for this form of anaemia liver extract owes its efficacy to its folic acid content. Between the third and fourth day after beginning treatment with folic acid in dosage of from 5 to 100 mgm. daily the reticulocytes in the blood began to rise and shortly afterwards the haemoglobin level and the red blood cell count began to improve. The reticulocytes usually reached a considerable peak in another three to four days and then decreased rapidly while the haemoglobin level and the red cell count continued to rise. The neutrophil leucocytes also increased and the hypersegmented forms gave way to normal cells within seven to sixteen days, sometimes a slight eosinophilia appeared. The platelets also increased in number soon after therapy was started. The bone marrow underwent a striking transformation and assumed a normal pattern within a few days. Unless other illnesses interfered, the patient's appetite rapidly improved, the colour returned and the irritability disappeared. Splenomegaly and hepatomegaly, although often persisting for some weeks after treatment eventually disappeared. In a follow-up period ranging from 3 to 20 months there were no recurrences of this type of anaemia in any of the patients who did not succumb to complications.

Inadequate diet and probably conditions interfering with proper absorption in the intestinal tract are possible factors producing the deficiency leading to this anaemia of infancy but it seems doubtful that these are the only factors concerned while the frequency of infections was striking. It is suggested that infections and nutritional deficiencies are aetiologically significant, while race, age and possibly prematurity and maternal anaemia are predisposing factors.

ZUELZER, W. W. Folic Acid Therapy in the Anaemias of Infancy and Childhood. *J Amer Med Ass.* 1946 May 4 v 131 No 1 7-8 1 chart.

This paper is another report on the effect of folic acid on the anaemia with a megaloblastic type of blood formation in the bone marrow which is not uncommon in white infants under the age of 18 months. [See ZUELZER & OGDEN above.] The characters of this anaemia are as follows. There is a severe normochromic anaemia usually but not invariably with macrocytosis there is a tendency toward leucopenia and neutropenia with giant metamyelocytes macropolycytes and hypersegmented neutrophils in the peripheral blood the platelets are diminished, sometimes to a severe degree and there is an increased tendency to bleeding and the bone marrow is frankly megaloblastic, resembling that of pernicious anaemia in relapse. Splenomegaly is common, but not constant some infection is usually present the nutritional history is usually poor and histamine-fast achlorhydria is often present although it does not persist after the anaemia is cured.

Twelve patients suffering from such an anaemia were treated with folic acid in synthetic form or by oral administration of concentrates rich in *Lactobacillus casei* factor the dosage of folic acid varying from 5 to 20 mgm. daily and the period of treatment from eight days to three weeks.

Three patients died of severe infections before the effect of the folic acid could be evaluated. In the remaining nine an unequivocal response was obtained, characterized by a reticulocytosis within a few days of starting treatment, a rise in the red cell count and haemoglobin level and a return of the bone marrow picture to normal. No relapses were observed in a follow-up period of ten months.

Folic acid therapy gave completely negative results in 18 children with anaemia of prematurity five with hypochromic microcytic anaemia, one with Mediterranean anaemia, two with chronic hypoplastic anaemia one with subacute myelogenous leukaemia, one with acute lymphatic leukaemia and one with sickle cell anaemia. In none of these patients was a reticulocyte response obtained nor did improvement of the anaemia occur even when large doses of folic acid, up to 50 mgm. daily, were given parenterally. The prophylactic use of folic acid from birth onwards over a period of months in premature infants did not prevent the development of anaemia comparable to that observed in control patients. A combination of folic acid and iron therapy did not increase or accelerate the effect of the latter in cases in which iron was indicated.

MERSKEY C. & BASARD E. Chronic Haemolytic Icterus resembling Acholuria Jaundice occurring in an African Native. *South African Med J* 1946 May 11 v 20 No 9 230-33.

An African native complaining of pains in both legs attributed to osteitis of the tibiae and with an enlarged spleen thought to be due to chronic malaria, was found on investigation to present features suggestive of acholuric jaundice. The erythrocyte fragility tested by saline solutions was increased, there was a slight reticulocytosis a positive indirect van den Bergh reaction, and increased urobilinuria without anaemia or evidence of haemolytic crisis. Owing to lack

of facilities it was not possible to measure the mean corpuscular diameter but in blood smears the cells appeared microcytic and dense which together with a mean corpuscular volume not far removed from normal was presumptive of spherocytosis. Some years previously the patient had had a severe illness lasting three months during which he had had many small haemorrhages from his nose and mouth and since that time he had had occasional febrile attacks. He had never noticed any jaundice and such of his family history as was available revealed nothing of significance. As he was free from symptoms he was discharged from hospital with a diagnosis of acholuric jaundice. He was subsequently twice admitted to hospital and the haematological findings again supported this diagnosis. The illness which brought him to hospital for the third time was a characteristic haemolytic crisis. For the first time he showed an appreciable anaemia and a well marked reticulocytosis. The bone marrow was typically erythroblastic and this reaction as well as a leucoblastic irritation could be detected in the peripheral blood films. During his crisis his red cell count dropped by nearly two million cells per cmm with only a slight increase in jaundice. There was a doubtful report of malarial parasites being present in his blood but this was not confirmed no significant auto- or hetero-haemagglutinins or lysins could be demonstrated, and no lytic drugs had been given.

The question as to whether the disease represented a congenital or acquired type of acholuric jaundice is open to some doubt but the comparative mildness of the condition is suggestive of the former. Against this however must be weighed the fact that the patient had probably been subjected to prolonged malarial infection which might have lead to an acquired haemolytic anaemia. The authors believe this to be the first case of chronic haemolytic icterus to be reported in an African native.

SEN A. K. Argemone Oil. *Indian Med Gaz* 1946 Mar \ 81 No 3 126-8
1 pl

Argemone mexicana is found practically everywhere in India since it will grow wild and in poor soil. The seeds being abundant and cheap they are used alone or with others as adulterants of mustard seed and argemone oil as an adulterant of mustard oil is known to be one perhaps the only cause of epidemic dropsy.

The author here describes three chemical tests for the oil as used at the Bengal Public Health laboratory Calcutta.

(1) The *Nitric Acid Test*—Pure nitric acid is thoroughly mixed by shaking with an equal quantity of the oil. On being set aside for the layers to separate the acid layer becomes red. When adulteration in small quantity up to 1 per cent. is present the colour is yellow and with increasing adulteration this deepens to orange and finally to red. Fallacies of this test are Sesame oil gives a yellow colour and artificial colouring matter may have been added. The test is therefore to be recognized only as a preliminary one.

(2) The *Cupric Acetate Test*—Five cc. of the suspected oil and 5 cc. of a known good oil are placed in two test tubes. 1 cc. of glacial acetic acid is added to each and the mixture is well shaken. Next 2 cc. of 3 per cent. cupric acetate in distilled water dissolved by heating in a water bath are added and the whole well shaken to mix and placed in a boiling water bath for 15 minutes with frequent shaking to prevent separation of layers. In the control tube the copper solution is sky blue. If argemone oil is present it is greenish with adulteration as high as 10 per cent. it is yellowish-green. This test is confirmatory of the nitric acid test and will detect adulteration of 0.5 per cent.

(3) The *Ferric Chloride Test*—This test as now used at the Bengal laboratory is a modification of that of S. N. SARKAR described in 1941 [see this *Bulletin*

ZUKLER W W Folic Acid Therapy in the Anaemias of Infancy and Childhood. *J Amer Med. Ass* 1946 May 4 v 131 No 1 7-8 1 chart.

VENOMS AND ANTIVENENES.

DUREX A. Les serpents venimeux du Congo Belge. 'Poisonous Snakes of the Belgian Congo. Institut Royal Colonial Belge Section des Sciences Naturelles et Médicales. Mémoires. (Collection in-8°) 1946 v 13 No. 5 45 pp. 11 figs on 5 pls. [12 refs.]

In his introduction the author remarks that the poisonous animals of the Belgian Congo are not of much importance—that accidents due to them are few and hence—the problems to which they give rise are negligible in comparison with those arising from pathogenic organisms—worms and insects. To stimulate interest and research he has therefore produced this brochure—as the field for study is virgin soil waiting for discoveries to be made. The present work is introductory in nature. Snakes of the Belgian Congo belong to five families Typhlopidae, Glauconidae, Boidae, Colubridae and Viperidae. Next he gives lists of Opisthoglypha and Proteroglypha Colubridae and Viperidae which are poisonous. Speaking generally, about one third of the snakes in the Colony are dangerous—of 724 captured at Stanleyville 331 were *Boodon olivaceus*, 75 were *Chlorophis irregularis*, both aglyphous Colubridae, 220 *Causus rhomboides* and 98 *Bitis nasicornis* Viperidae. Then follow some notes on 12 species—their size, habitats, feeding habits and, after general remarks on the poisons of Colubridae and Viperidae such as are found in all textbooks, he offers some observations on Congo species and the effects of their bites—both garnered from the reports of others. No original work is recorded.

This article would serve well as an introductory chapter to detailed investigation of the subject as stated in the title and in his conclusions the author asks for information on the following three points: (1) Return of cases of poisoning and abstract reports on the symptoms. (2) Geographical distribution of the poisonous snakes of the Belgian Congo. (3) Study of the venoms of those most common or most dangerous with a view to preparing antivenenes.

DERMATOLOGY AND FUNGUS DISEASES.

HAILEY H. Treatment of Creeping Eruption (Larva Migrans). *Southern Med J.* 1946 Mar v 39 No. 5 371-2. 1 fig.

At a meeting of the Section on Dermatology and Syphilology, Southern Medical Association, Cincinnati, in November 1945 the author described four cases of creeping eruption treated by him with onion poultices.

The poultices were prepared by spreading white vaseline over a piece of gauze and adding finely grated onion in a thickness of about $\frac{1}{4}$ to $\frac{1}{2}$ of an inch the poultice being covered with waxed paper or some other impervious material. It was applied nightly for three to seven nights. In his limited number of patients the treatment proved as satisfactory as the use of ethyl chloride in similar patients.

The author claims that this treatment has the advantage of cheapness and freedom from pain as compared with ethyl chloride which had proved extremely painful.

In the discussion which followed, seven speakers quoted their experience in the treatment of larva migrans with such a variety of remedies as arsenicals, antimony compounds chrysarobin ethyl acetate ethyl chloride and carbon dioxide snow.

These opinions confirm the well known experience to which the author himself testifies that the large number of treatments for creeping eruption is good testimony to the fact that a better one is greatly to be desired. [Whether that desire has been satisfied by the treatment described would require considerably more evidence and the author's report has been made in the hope that other dermatologists will attempt to determine its true value. He has in any case added one more remedy to the already lengthy list of measures adopted against this distressing condition.]

NOVACOVICH G G Observations and Data on Prevention of Poison-Oak Dermatitis. *U.S. Nav. Med. Bull.* 1946 June v 46 No 6 811-19 1 fig [15 refs.]

The so-called Poison-oak is a species of Poison Ivy *Toxicodendron diversiloba* though it has an oak like leaf it is not related to the oak in any way. It contains an allergenic oleoresin the same as that in poison sumac and Japanese lac trees. Injection of the antigen produces some degree of immunity but not great. Oral administration gives better results though the immunity is temporary it lasts for 5-6 months. It was found that about 2 cc. of the oil diluted and administered over a period of 8-9 months was sufficient. One method was to give as an initial dose 0.5 mgm. of ether-extracted residue and gradually to increase till at the end of 45 days the day's dose was 150 mgm.

Various antidotes and protectives were tried chlorinated lime antigas ointments perborate ointment among them. The best was found to be 10 per cent chlorinated lime in an ointment basis consisting of —

Cetyl alcohol	35.1
Stearyl alcohol	5.3
Cerestin	3.5
Castor oil	20.8
Mineral oil	21.9
Duponal WA pure	1.7
Sodium perborate	10.0
Boric acid	0.7

It inactivates (or destroys) the toxic principle and is also usable prophylactically.

H Harold Scott

WEIDMAN F D & GLASS F A. Dermatophytosis and other Forms of Intertriginous Dermatitis of the Feet. A Comparison of Therapeutic Methods. *Arch. Dermat. & Syph.* 1946 Mar v 53 No 3 213-25 1 chart

There is acute need for a satisfactory means for keeping the feet of fighting men in good condition in which connection intertriginous dermatitis poses a large problem. As to specific curative agents dissatisfaction is general particularly

in respect to the recurrences that are so notorious. Thus far salicylic acid, iodine and chrysarobin are the anchors but the last two particularly chrysarobin are capable of producing a chemical dermatitis and hence should be employed only under expert medical supervision. In view of the urgent need of better chemotherapeutic measures against foot ringworm the authors undertook a carefully controlled experiment in treatment of intertriginous dermatitis on 117 life-sentence prisoners in a penitentiary. Six preparations were tested, as follows: (1) Cresatin Sulzberger (metacresylacetate) used at full strength; (2) boric acid foot powder (5 per cent. boric acid in talc); (3) ointment of benzoic and salicylic acids (3 per cent. salicylic and 12 per cent. benzoic acid in a petrolatum base); (4) "Iodolate" (iodocholeate) used as a 20 per cent. ointment as supplied by the maker; (5) Pomeio (potassium mercuric iodide in 1.2 per cent. aqueous solution); (6) Zephiran chloride (a mixture of alkyl dimethyl benzyl ammonium chlorides). All the medicaments were applied by the prisoners themselves according to mimeographed instructions and the results were classified as Cured, "Nearly cured," "Improved."

Stationary and "Worse." Considering only the "cured" and "nearly cured" cases two preparations stood out apart from all the others in effective ness: these were cresatin and the boric acid foot powder—the foot powder being nearly as effective as cresatin. When the improved results were added to the "cured" and "nearly cured," the salicylic-benzoic ointment entered the picture and all three preparations seemed to be about equally effective in causing improvement with satisfactory results in about three-quarters of the cases. This suggests that while the salicylic-benzoic ointment is as effective as the other two preparations in bringing about clinical improvement its action seems to stop short of cure: this tends to bear out the view sometimes expressed, that the effect of salicylic acid ointments is merely to remove the superficial epidermal scales. The results from preparations 4, 5 and 6 were frankly disappointing: in fact 28.5 per cent. of the patients treated with iodolate were rendered "worse" and in some of the cases severe reactions even amounting to suppurative or chemical dermatitis occurred.

The authors were not able to confirm the views of Lewis that *Trichophyton interdigitale* and *T. purpurum* cause distinctive lesions and that lesions caused by *T. purpurum* are specially resistant to treatment. On the contrary they obtained cures in 50 per cent. of the *T. purpurum* infections and in only 32.4 per cent. of the *T. interdigitale* infections. The *T. purpurum* infections were almost confined to men below middle age.

J. T. Duncan

GOMEZ, J. E. Tokelan in Guatemala. *Arch. Dermat. & Syph.* 1948 Mar., v. 53 No. 3: 243-8. 3 figs.

This paper gives a good account of the history and nomenclature of Tokelan disease (tinea imbricata) first described by William Dampier in the Philippines in 1688. In the South Seas the disease is associated with the warm and very humid climate of the coastal areas but in Guatemala it occurs most frequently at distances of 80 to 170 kilometres from the sea coast and at an altitude of 3 000 to 9 000 feet. Clinically and mycologically the Guatemalan disease is similar to that of the South Seas: it is commoner in women than in men and the predisposing factors seem to be malnutrition and neglect of personal hygiene. Treatment on the whole gave only disappointing results except in the case of sodium iodoxyquinolinesulphonate which showed considerable promise and merits further trial.

To obtain clear photographs of the lesions the skin was rubbed with a compress saturated with 10 per cent. gentian violet, and the following day after careful washing only the diseased scales were found to retain the dye.

MOORE M & ACKERMAN L V Sporotrichosis with Radiate Formation in Tissue. Report of a Case *Arch Dermat & Syph* 1946 Mar v 53 No 3 253-64 3 figs. [Refs in footnotes]

In the lesions of sporotrichosis *Sporotrichum schencki* is sometimes seen as a yeast like cell or a small collection of cells surrounded by eosinophil club-shaped bodies similar to those seen in actinomycosis and some other fungus diseases. The appearance in sporotrichosis is sufficiently rare to warrant publication of the case. SPLENDORE who was the first to describe the appearance (in 1908) named the fungus *Sporotrichum asteroides* believing it to be a new species but the organism when studied in saprophytic life was found to be the typical *Sporotrichum schencki*. The club-bodies are probably formed by the host tissues although the species or the peculiar strain of the fungus parasite may be a determining factor in their formation. J T Duncan

WILLETT F M & WEISS A Coccidioidomycosis in Southern California Report of a New Endemic Area with a Review of 100 Cases. *Ann Intern Med* 1945 Sept v 23 No 3 349-75 8 figs [33 refs.]

Unsuspected exposure to infection by *Coccidioides immitis* during military training of United States troops in desert areas of California Texas Arizona and New Mexico has revealed hitherto unknown endemic areas of coccidioidomycosis. The diagnosis of infection rests chiefly on a routine use of the coccidioidin skin test a positive reaction occurring in a man on whom a previous test had given a negative result being accepted as satisfactory evidence of recent infection. Although a majority of the positive reactors are symptomless the authors were able to analyse the symptomatology of 100 cases of primary coccidioidomycosis in four of which (all negroes) the disease progressed to the grave disseminated form. Fever of some degree was present in 80 per cent of the cases and it lasted on the average less than a week. chest pain usually aggravated by deep breathing or coughing in 73 per cent. cough in 64 per cent. was almost invariably non productive but the transient appearance of blood streaked sputum was noticed in 3 per cent. joint manifestations chiefly arthritis in 8 per cent. erythema nodosum in 4.4 per cent. and erythema multiforme in 2 per cent. (of 135 patients) malaise a vague symptom, in 43 per cent. anorexia was definite in 30 per cent. headache in 27 per cent was of a generalized type, and was so severe, in some cases as to justify spinal puncture. chills occurred in only 12 per cent.

The X ray picture of the chest usually showed some degree of parenchymal infiltration ranging from a minimal lesion to consolidation often associated with hilar adenopathy and thickening and sometimes a pleural exudate. Pulmonary cavitation was detected in 6 per cent. of the cases and was always a late complication of the acute stage its typical thin walled character becoming apparent only after resolution of the surrounding consolidation. The lesions of bone were well-circumscribed areas of destruction with some tendency to bone proliferation and elevation of the periosteum.

Dermal sensitivity to coccidioidin is evidence of present or past infection. It is usually demonstrable in two to four weeks from the time of infection and it persists for an indefinite time. The reaction is apparently specific but it is absent in the earliest stages of the disease (two to four weeks) and in the state of allergy associated with severe disseminated disease. Eosinophilia is present in some degree ranging from 5 to 18 per cent. in most cases during the initial few weeks of the disease. Serum tests are of particular value both in diagnosis and prognosis a declining antibody titre being an indication of progressive recovery while a persistently high titre for complement fixation

suggests an unfavourable issue. As primary coccidioidomycosis is essentially a pulmonary infection the examination of the sputum (when obtainable) offers a means of diagnosis. However the spherules of *C. immitis* are difficult to detect even in specimens of sputum cleared by caustic potash solution and although the fungus was cultivated from the sputum of 61 per cent. of the present series of cases it was found by microscopy in only 28 per cent.

For a more detailed analysis this important paper should be consulted in the original.

J T Duncan.

TROPICAL ULCER.

WEBB J G Tropical Ulcers and Penicillin. *Brit Med J* 1946 July 13 49-50.

It was to be expected that as penicillin became more widely available it would soon be added to the already imposing list of remedies which have been given a trial in the treatment of tropical ulcers.

In this paper the author describing the results of seven years' study of tropical ulcers in South China claims a remarkable response on their part to treatment with penicillin. The claim is however based upon 10 cases only.

The aetiology of tropical ulcer is discussed, and the clinical stages are described. The author accepts the specificity of *B. fusiformis* [*Fusiformis fusiformis*] as a causative organism and its disappearance as a criterion of cure. Six of the ten cases also showed the presence of mixed cocci. The age of the ulcers before treatment varied from 3 days to 6 months (in two cases the ulcers had relapsed after primary occurrences of five months and three years respectively).

Penicillin was given locally a solution of 500 units per ml. being applied on gauze twice daily and by intramuscular injection of 15 000 units three-hourly up to a maximum of 80 000 units (except in mild cases).

Results were very good, the fever and inflammation subsiding in one to three days when the ulcer presented a smooth granulating surface. Further treatment was similar to that of varicose ulcers. The time of final healing is not recorded. The author enters a plea for the widespread use of penicillin as it becomes available.

[HAMM and QUARY (this Bulletin 1945 v 42 495) and MOREAU and QUARY (*ibid* 1946 v 43 378) described 18 and 19 cases respectively of tropical ulcer treated with penicillin with apparently very good results. It is a matter of some doubt whether the beneficial effects in all of these cases were due to elimination of the *F. fusiformis* or as appears to be more likely the destruction of the mixed cocci. The treatment merits wide trial, which will no doubt be forthcoming as supplies of penicillin become available.]

MISCELLANEOUS DISEASES

MIRICK G S, ZIMMERMAN H M, MAWER G D & HUMPHREY A A. Melkoidosis on Guam. *J Amer Med Ass.* 1946 Apr 20 v 130 No 16 1063-7 8 figs.

This paper describes two cases of melkoidosis in American service men, developing after some six months on Guam. Both cases ran an acute course terminating fatally after five and seven days respectively. At autopsy millary

abscesses were present in the lungs liver spleen and kidneys. *Pf. whitmorei* was isolated from the blood stream on the 5th day of disease in the second case and from the visceral lesions in both cases *post mortem*. These strains grew readily on the usual media including Koser's citrate medium under aerobic conditions and produced acid but no gas from glucose and galactose in two days lactose mannitol, xylose maltose sorbitol and adonitol in six days and sucrose in nine days rhamnose dulcitol and trehalose were not fermented. Ammonia was produced from peptone nitrates were reduced to nitrites methylene blue was reduced and catalase reaction on inoculation into male guinea pigs produced a typical Strauss reaction on inoculation into laboratory tests showed that Systemic penicillin (a total of 200 000 units in the first case the amount in the second being unspecified) was without effect and laboratory tests showed that these strains of *Pf. whitmorei* were insensitive to as much as 35 units of penicillin per ml. Growth of an inoculum of about 1 000 bacteria in tryptose phosphate broth was however completely inhibited by sulphadiazine in a concentration of 15 micrograms per ml in 18 hours at 37 C.

HERBUT P A. & KINSEY F R. Transitory Pulmonary Infiltrations (Loeffler's Syndrome) in Rabbits. *Arch Pathology* 1946 May v 41 No 5 489-502 3 figs [Refs in footnotes.]

Loeffler when first reporting cases of what has since come to be known as Loeffler's syndrome—eosinophilia with transitory pulmonary infiltration—stated that recovery took place in all so that no examination of the pathological changes was possible but it was thought that the lesion was a pathological tissue reaction probably produced by a variety of antigens and comparable to erythema nodosa [sic] of the skin.

The authors have carried out experimental work on rabbits sensitizing them to horse serum by repeated subcutaneous injections then exposing the trachea and instilling horse serum intratracheally a single dose of 5 cc in one group 0.5 cc hourly for 5-12 doses in one or two days in a second group. Systemic disturbance was slight but by \rav pulmonary infiltrations were seen which cleared in 1-2 weeks the tracheal secretions contained eosinophiles and the submucosa of the trachea and bronchi was congested and oedematous and showed infiltration with eosinophiles but there was no blood eosinophilia as in human cases of Loeffler's syndrome and the lung infiltrations were more persistent. The authors conclude that Loeffler's syndrome is an allergic inflammation of the lungs and that one route by which the allergen invades is that of inhalation. [In view of the absence of eosinophilia and the longer persistence of pulmonary signs the condition produced in these experimental rabbits differs from Loeffler's syndrome in man and the conclusion is therefore hardly justified.]

"Of the 18 plants investigated the following four plants were according to the literature available to the authors for the first time proved to be toxic *Tetragonia Schenkii* Schinz. *Encephalartos Lehmannii* (E. & L.) Lehm. *Moraea trita* var *foliata* N.E Br and *Schizocarphus nervosus* (Burch.) F v d.M.

The toxicity of the pupae of *Melasma circophora* Meyr was also investigated."

WAHL, P N Needle Biopsy of the Liver Technique and Diagnostic Application. *Indian Med Gaz* 1946 Mar v 81 No 3 130-34 7 figs. (6 on pl.)

A plea for the taking of small portions of liver tissue by means of the Vim-Silverman needle as an aid in the diagnosis of obscure liver conditions. The bleeding time clotting-time, prothrombin-time and prothrombin concentration are first determined as a routine, and any serious tendency to bleeding passive congestion of the liver suspected liver abscess or suppurative cholangitis are considered to be contra-indications for the operation. Vitamin K is injected intramuscularly if the prothrombin concentration is 50-70 per cent. if lower than that the operation should not be done. It is also given to all patients with jaundice. The track for subsequent insertion of the needle is anaesthetized and the needle then is passed half an inch into the liver substance the trocar having been withdrawn the inner split-needle is passed into the cannula then the outer needle is advanced over the split-needle, to compress the latter and secure the piece of tissue and rotated once to cut the base of the core. With enlarged and palpable livers entry is made below the rib margin in front otherwise at the 8th or 10th intercostal space in the mid or anterior-axillary line.

Six cases are mentioned in which this biopsy examination assisted or confirmed clinical diagnosis and others are referred to e.g. one of lardaceous disease in a tuberculous patient in whom the liver condition had been thought to be cirrhotic.

DAVID W A L. Factors influencing the Interaction of Insecticidal Mists and Flying Insects. Part II. The Production and Behaviour of Kerosene Base Insecticidal Spray Mists and their relation to Flying Insects. *Bull Entom Res* 1946 May v 37 Pt 1 1-28 1 fig [17 refs.]

The author uses the apparatus described in a previous paper [this *Bulletin* 1946 v 43 679] to investigate production and behaviour of insecticidal spray mists. The following factors are discussed —

(1) Those concerned with atomization of the spray —Design and dimensions of the atomizing nozzle spraying pressure and air/liquid volume ratio viscosity surface tension and the density of the spray liquid.

(2) Factors concerned with passage of spray droplets through the air — Composition of the droplets size of the droplets and the influence of evaporation rate of fall of the droplets

(3) Properties of the mist in relation to insects at rest or in flight — Composition of the mists and their changes with time contamination of motionless and flying insects transit volumes of the latter

In the experimental section mists of different composition were sampled at various times after evolution. A quantity of kerosene or other oil dyed with Sudan III was sprayed into the cabinet and samples were collected from the mist (i) by a sintered glass funnel from which the dyed oil was recovered and measured colorimetrically or (ii) by a sliding impactor or a cascade impactor. The design of the slide impactor is described. These two impactors give indications of the drop-size distribution for all drops except the very smallest. The quantity of spray which fell to the floor was estimated by a glass plate from which the oil was washed and estimated colorimetrically. The results showed that —

(1) Increase in air pressure (7.5 to 20 lb./sq. in.) for atomization produces a mist with a larger proportion of small droplets so that a smaller amount falls to the base in a given time.

(2) Pre-spraying of the chamber at the rate of 180 cc./1 000 cu. ft. greatly reduced the evaporation of the droplets of kerosene subsequently sprayed at 12.8 cc./1 000 cu. ft. and much bigger drops resulted. The theoretical saturation concentration of refined kerosene in air at room temperature is about 1 700 cc./1 000 cu. ft. so that the vapour slows down evaporation of droplets at quite a low fraction of the saturation value. Pre-treatment of this type with the non-volatile white oil P31 had no effect on the drop size of the subsequent mist.

(3) The mists produced by kerosene were compared with mists of the very volatile petroleum ether and the non volatile oil P31. The first evaporates to a mist of extremely small particles and only 5 per cent. is deposited on the floor after ten minutes compared with 20 per cent. of kerosene and 70 per cent. of P31. The drops of the P31 are generally of larger range than those of kerosene. (All oils were sprayed at a spraying pressure of 12.5 lb./sq. in. and at the rate of 12.8 cc./1 000 cu. ft.)

The very fine droplets are too small to impact but slip round the air-stream past a flying insect. Consequently the mists of very small drops of insecticide dissolved in petroleum ether are less effective than the same quantity applied in kerosene. This difference is greatest shortly after spraying before the kerosene droplets have evaporated to very small dimensions.

(4) The addition, to a kerosene spray of 5 per cent. non volatile oil does not greatly increase the amount falling to the base in ten minutes but it does produce a mist of rather larger droplets. Consequently it is more effective in killing flying insects (as shown by tests with *Aedes aegypti*) since they pick up a larger dose of insecticide.

(5) An increase in the quantity of liquid sprayed from the rate of 12.8 cc./1 000 cu. ft. to double or quadruple this amount reduces the speed of evaporation of droplets and increases the proportion which falls to the base.

(6) By means of the sliding impactor the drop size distribution of sprays can be measured. Half a minute after spraying kerosene the drops range from 3 to 20 microns in diameter but these have all evaporated to less than 5 microns in four minutes. If however 5 per cent. non volatile oil is added, any larger droplets (up to 13 microns) can be preserved up to four minutes.

McGOVERN E. R., FALES J. H. & GOODHUE, L. D. New Formulations of Aerosols dispersed by Liquefied Gases. *J. Econom. Entom.* 1946 Apr v 39 No 2, 216-19 1 fig.

Tests of various liquefied-gas aerosol preparations against houseflies and mosquitoes were made in a Peet-Grady chamber. Aerosol formulae showing great improvement in toxicity over the original formula have been developed by increasing the non-volatile content. The original contained 2-4 per cent. non volatile material; this can be increased up to 15 or 20 per cent. with improving efficiency. Above 20 per cent. however the efficiency definitely declines. This is probably because aerosols with low non-volatile content evaporate to minute particles too small to impact on the insects. Increasing the non volatile content enlarges the final size of the droplets and improves chances of wetting the insects. Above a certain size however the drops fall rapidly to the floor. Improvements in formula can also be made by adding more sesame oil or other synergist or by adding DDT or benzene hexachloride. Details of several effective formulae are given. *J. R. Bursine.*

GOODHUE L. D. & RILEY R. L. Particle-Size Distribution in Liquefied-Gas Aerosols. *J. Econom. Entom.* 1946 Apr v 39 No. 2, 223-6 6 figs.

A method of determining the particle size of liquefied-gas aerosols is described. The aerosol is projected into a settling chamber from a hole in the middle of the base and allowed to settle for two hours on to slides coated with mannitan monolaurate which is oleophobic and retains the oil drops as lenses. By various measurements the volumes of drops which produce lenses of different sizes can be estimated, and the numbers of each size can be counted. Distribution curves of particle size are given for aerosols of different composition. The most effective concentration of non volatile material seems to be about 15 per cent. From insecticidal tests it appears that drops of insecticide 2 to 10 microns in radius are the most effective in killing free-flying insects. *J. R. Bursine.*

GLASGOW R. D. & COLLINS D. L. The Thermal Aerosol Fog Generator for Large Scale Application of DDT and other Insecticides. *J. Econom. Entom.* 1946 Apr v 39 No 2 227-35 24 figs. on 2 pls.

Ordinary insecticide atomizers produce droplets of the order of 50 to 150 microns in diameter. The smoke generators employed for military purposes (screening) evolve drops of oil 0.5 to 0.75 microns in diameter but by suitable modifications they can be made to produce larger drops. A suitable size for insecticidal use appears to be about 10 to 50 microns. The authors have made some trials of two types of thermal fog generator for control of insects. [Very few observations are given: the tests are described as successful etc. or "dead insects swept up for a week afterwards."] The two generators used in the trials were—

(1) The HOCHBERG-LA MER type which evolves droplets by the use of superheated steam and

(2) The TODD Thermal Generator which employs a temperature-controlled blast of hot air to atomize the insecticide.

Successful non-residual control of houseflies, mosquitoes, "punkies" (gnats), blackflies, stable flies etc. was obtained by the use of an aerosol produced from 5 per cent. DDT in kerosene used at the rate of 0.2 lb. of DDT per acre. This

type of aerosol was also used in buildings for control of cockroaches and clothes-moth larvae but the results are not clearly stated.

SCHROEDER, H O & LINDQUIST A W. *Sprayers—*for dispensing Concentrated Insecticides. *Soap* New York 1946 June 1 22 No 6 149-51 & 173 3 figs.

Small compact sprayers from $\frac{1}{2}$ to $1\frac{1}{2}$ inches in diameter and $4\frac{1}{2}$ to 14 inches in length have been made for atomizing concentrated insecticides in household use. The sprayer plan consists of a cylindrical liquid tank containing the insecticide carried in a compression cylinder which slides up and down over the liquid cylinder. At the base of the latter is a leather washer valve

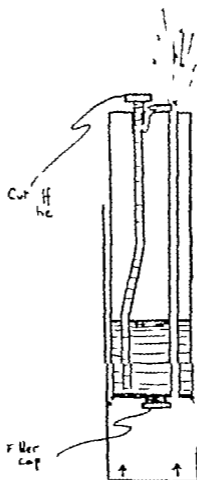

Diagram illustrating the essential details of the pocket size spray atomizer redrawn in simplified form from figure 1 in the original paper by Schroeder and Lindquist in *Soap*

in the centre of which is an oil resistant gasket for filling the liquid reservoir. The movement of the compression cylinder compresses air which is carried up through a tube going right through the liquid tank. The liquid insecticide is drawn up by suction from another tube which runs to the base of the liquid cylinder while the upper surface is set at right angles to the air jet. The movement of the outer cylinder over the inner one thus generates the air to atomize the insecticide. When not in use a screw valve in the liquid tube is closed to prevent leakage whatever the position of the apparatus.

J R BURRINE

WIEMANN R. & ZICKERNAGEL R. Eine neue Methode zur Bekämpfung der Mückenbrut. [A New Method of controlling Mosquito Larvae.] *Gesundheit u. Wohlfahrt* 1946 June v 26 No 6 297-332, 6 figs. [28 refs.]

Methods of controlling mosquito larvae are briefly reviewed, and the qualities of an ideal insecticide for the purpose are enumerated. The main body of the paper deals with experiments with Gyron a powder preparation containing 5 per cent. DDT compounded for larvicidal use.

Anopheles larvae in water that has been dusted with Gyron become restless in five to ten minutes after fifteen to twenty minutes they frequently fall to the bottom and have difficulty in regaining the surface. Tremors begin and continue for a long time while the larvae finally are unable to leave the bottom. Similar signs of intoxication are shown by *Culex* larvae but less rapidly since owing to their position at the surface they are less readily contaminated by the powder.

Pupae of both types of mosquito are resistant to DDT applied in this way. This is because the insect in this stage is protected by the cast skin of the last larval stage in which it is lying. There is one part of the body in the abdominal region where the new cuticle is still in contact with the old one. This part is sensitive to DDT but normally is protected from the particles falling from the water surface because the abdomen is tucked under the body. If this position is disturbed, or if an emulsion of DDT is used, the pupae are killed.

From the outline area of the larva the amount of active ingredient which falls upon it can be calculated. Thus it can be estimated that with a dusting of Gyron at 2 gm. per sq. m. a larva receives only 0.001 mgm. of DDT. This dose is sufficient to incapacitate all *Anopheles* larvae in about two hours and all *Culex* larvae in four hours. The speed of action depends on the temperature. Experiments with *Anopheles* larvae showed that with a dusting of 3 gm. Gyron per sq. m. all larvae sank in two hours at 18-25°C. In three and a half hours at 16°C. in six hours at 13°C. and in ten to eleven hours at 6°C.

In nature it may happen that a pond dusted with Gyron will be cleared by the action of wind or rain after a certain period. Tests were therefore carried out to determine how long an exposure is necessary to result in the death of all larvae. Experiments were done at different temperatures using 3 gm. Gyron per sq. m. in all cases. After various times under the toxic dust, the larvae were removed in a pipette to clean tanks. It was found that *Anopheles* larvae were killed by the following exposures to Gyron films—20 minutes at 30°C. 25 minutes at 25°C. 35 minutes at 20°C. 55 minutes at 15°C. and 85 minutes at 10°C.

Experiments with various stages of larvae showed that the resistance increases with age from first stage to fully grown larvae. The latter were accordingly used in most of the experiments.

Tests were made with Gyron to determine its effects on aquatic organisms other than mosquitoes. A normal dusting was harmless to newts and water snakes and also to Crustacea such as *Gammarus*, *Cyclops* and *Daphnia*. Of the insects those forms which live on or visit the surface (water skaters, water beetles, etc.) were killed though, surprisingly enough, the bugs *Neops* and *Ranatra* were not affected when obviously contaminated.

Bottom-living forms were not harmed except in clean glass dishes, for they are normally protected by vegetation and detritus. Plants, coelenterates and protozoa were unaffected.

Comparative to atomized. It is done with various other mosquito larvicides to compare. Non-residual controls were used at concentrations of 5 per cent. and applicable flies etc. was 0 per sq. m. All were found to have some disadvantages. DDT in kerosene used was effective but is poisonous to mammals,

etc Phenothiazine (thiodiphenylamine) and hexachlorocyclohexane (crude Gammexane) are effective but soon lose their toxicity. Gesarol a horticultural preparation of DDT sinks too quickly to the bottom. None was as satisfactory as Gyron.

Several small practical trials on still lakes with Gyron are described in some detail. It is concluded that it should be applied at the rate of 3 gm. per sq m. and this will prevent breeding of mosquito larvae for three to four weeks. Therefore two or three dustings should suffice to prevent breeding throughout the summer breeding season.

GOLDING F D A New Method of trapping Flies Bull Entom Res 1946
May \ 37 Pt 1 143-54 2 figs J R Busvins

This new method consists of the use of Até adhesive the coagulated latex of the vine *Carpodinus hirsula* found in Nigeria. This latex is mixed with some vegetable oil and produces the adhesive which is then applied to wire which are suspended in kitchens etc. The fresh substance appears to attract the flies after a week the viscosity decreases and many insects escape. [As a control measure this technique was of some value but with the use of residual DDT it is probably already obsolete. It may be useful in making a survey of flies.]

Some interesting figures are given showing the flies captured at Ibadan. Houseflies mainly *Musca domestica* were trapped over two years in 17 kitchens. In all 272 498 flies were counted. The maximum catch occurred during the summer rains when the temperature was high and breeding accelerated and when desiccation was not a serious problem to the flies. Flies were captured throughout the day but in the greatest numbers at dusk. Flies were captured cent. of the total catch.

SMITH A. & GREAVES D P A Case of Nylasis due to Warble-Fly Larvae Brit Med J 1946 July 27 120-22, 3 figs [11 refs.] Kenneth McIlanby

MICHENER, C D Observations on the Habits and Life History of a Chigger Mite *Eutrombicula batatas* (Acarina: Trombiculidae) Reprinted from Ann Entom Soc America 1946 Mar \ 39 No 1 101-18 34 figs on 5 pls. [12 refs.]

This mite is of interest mainly because of its relationship to the Trombiculids which transmit scrub typhus. This paper contains no new information of direct medical importance but various biological data are given which may assist those working on the disease-carrying mites. The life-history and its various stages are described in detail and the duration of these stages is also given. The eggs laid singly in damp soil develop in about four days but the larva remains another week in the shell. This is called the deutovum. The active larva may take 14 days to find a host on which it remains from two to ten days. It is active for up to four days after feeding but then becomes quiescent as a protonymph. [This is often called the nymphophane by other authors.] This turns into the nymph whose active life is from 16 to 45 days. There is another week of inactivity as a preadult before the final moult. The adult lives up to 45 days. The food of the nymph and adult has not been determined but it is suggested that it may be fungal. The technique used is described. [For details see this Bulletin 1946 \ 43 797]

Kenneth McIlanby

JAYEWICKREME, S. H. A Note on the Breeding of Nymphs of the Trombiculinas (Acarina) Reprinted from *Ceylon J Sci. Section B Zoology* 1946 May 30 v 23 Pt. 2 85-8

Scrub typhus research has always been held up because of difficulties in the handling and breeding of the vectors in the laboratory. So far no really satisfactory technique of breeding the Trombiculid mites has been described, though several workers have suggested that they have discovered improved methods which, on further investigation, show little advance. The author of the present paper is less ambitious in his claims, and only sets out to show how to obtain the nymphal stage from the larva, a step which has often been accomplished before, but not with the same high percentage of success. Engorged larval mites were kept in glass cells on wet cellulose wadding. The larval skins could usually be correlated with the nymphs which emerged, an important step in obtaining a correct description of the various stages in the life-history.

SWARTS W B & WANAMAKER J F. Skin Blisters caused by Venous Beetles. *J Amer Med Ass.* 1946 June 15 v 131 No. 7 594-5 4 figs.

The author states that more than 200 species of blister beetles have been found in the United States. The species depicted in this paper *Epicauta cincta* is about 1.5 cm. in length, a deep purple in colour. The insect will crawl over the skin without doing any harm unless disturbed, irritated, or hindered by clothes. Then its body exudes an irritating blistering fluid, but the blistering does not appear for 24 hours or so by which time the fact of contact may have been forgotten. The bullae it produces are round dome-shaped, hemispherical, without any surrounding erythema. Opening to release the fluid and the application of a mild antiseptic bring about complete healing without any scarring, in 10 days. Diagnosis has to be made from bullous dermatoses such as pemphigus dermatitis herpetiformis dermatitis venenata and inflammatory bullae from thermal or chemical agents.

H. Harold Scott.

LABORATORY PROCEDURES.

DR BURGH, P. M. Notes on Field's Stain. *Med J Australia* 1946 Apr 20 v 1 No. 16 544-5.

The author of this paper refers to some of the factors involved in the success or failure of Field's stain to produce good staining of the malaria parasite principally in achieving a red chromatin dot and blue cytoplasm.

He discussed the drawbacks in the use of preparing modifications of Field's Solution 1 and describes a modification of McNeal's acid oxidation method used by LILLIE in preparing Giemsa stain which was found satisfactory in preparing Field's first solution [this *Bulletin* 1945 \ 42 414 1944 \ 41 74]

DE BURGH also found erythrosin slightly preferable to eosin in Solution 2. He discusses the action of Field's stain at length and draws particular attention to the fact that when the final layer of haemoglobin left in the blood-film becomes too thick the chromatin appears blue-black. The success or failure of the stain depends mainly on the thickness of the film. He points out that preliminary removal of haemoglobin can be done in a variety of fluids none of which has any real advantage over distilled water. He describes a modification of technique which whilst it involves little increase in staining time extends the range of thickness of the films over which good staining may be obtained.

The paper contains a wealth of technical detail and in order to appreciate its considerable practical value it should be read in the original

H J O D Burke-Gaffney

RATCLIFFE A. W A Note on Staining Plasmodia. *Science* 1946 May 17 630-31

The author suggests that our conception of plasmodial staining reactions may be incomplete

(1) Blood infected with *P. vivax* (produced clinical and typical smear positive malaria upon therapeutic inoculation) smeared and stained with Wright's stain failed to reveal any parasites

(2) Similar blood which showed numerous parasites in fresh unstained blood failed to reveal any parasites in stained smears

(3) Smears of blood with numerous parasites (*P. vivax*) which stained readily when first smeared could not after transportation (Texas to Indiana) be stained to show organisms of diagnostic acceptability

The author suggests that the solution of the problem of staining these organisms might be helpful in the ancient and recurring problem of smear-negative patients progressing to necropsy demonstration of plasmodia.

The pH of the buffer age of smear and brand of stain are important factors which determine the quality of the result. Old smears require a lower pH and longer staining time, and alkaline buffer produces a dark [blue] smear while an acid buffer produces a red smear. The author's chief problem was failure to obtain (red) staining of the chromatin. Despite the red cast with acid buffers it was the blue which seemed to stain the nuclei of the leucocytes rather than the azure components of the stain. It is recommended that azure staining of the chromatin is improved by using alkali as a preliminary bath rather than as a medium for the stain and sodium carbonate and ammonium hydroxide were found to be satisfactory. Fresh smears may be given brief exposure to pH 8-9 after fixation and old smears to a stronger alkali, but the exact concentration or time has not yet been determined? By bathing old films in strong alkali and subsequently staining for 24 hours in Giemsa or Wright's stain satisfactory results can be produced. The possibility of shortening the period of staining by adding a penetrant such as Tergitol 7 is being investigated.

[It is well known that old unstained films are extremely difficult to stain satisfactorily. The blood corpuscles become very hard and fixation is unnecessary even when watery stains (Giemsa) are used. Such films stain a deep blue. The reviewer has found that temperature is an important factor - old films kept at 50°F stain better than do similar films kept at 80° or 90°F]

CHEMLOCK, R. L. & MULLER H. E. Use of Wetting Agents in Histological Fixatives. *Science* 1946 June 21 731-2.

On the grounds that the speed of penetration of a tissue fixative probably enhances its quality the authors carried out a series of experiments in which three wetting-agents were added to carefully prepared solutions of nine different standard fixing solutions. Sheep cerebrums and human liver were found to be useful test tissues and pieces of these one inch square, were placed in 250 cc. of each of the nine fixatives for 24 hours. They were then sectioned and the degree of penetration estimated grossly by the use of colouring agents. The preparations were then carefully studied microscopically. The fixative solutions employed were Zenker's Carnoy's Helly's, Bouin's Allen's, Gilson's, Orth's Vandegrift's and 10 per cent formalin. Each was modified by the addition of three aliphatic substances known to have the quality of decreasing surface tension. The aliphatics used were Tergitol-7 Tergitol-4 and Tergitol-OS. These were all used in the ratio of three drops to 100 cc. of fixative. The authors found no correlation between the various fixatives their pH component ingredients or supplementary Tergitol and the degree of penetration or the quality of fixation staining and shrinkage. They did find however that in the case of Allen's, Orth's, Vandegrift's and Zenker's fluids and also 10 per cent formalin, Tergitol-4 improved fixation and staining. Tergitol-OS produced a similar result when added to Zenker's fluid.

All other combinations of fixatives and detergents showed either no improvement or a decrease in the quality of fixation and staining.

REPORTS SURVEYS AND MISCELLANEOUS PAPERS

INDIA. Annual Report of the Public Health Commissioner with the Government of India for 1943 and 1944 [BOZMAN C. A.]. 39 pp 1 folding map 1946 Delhi Manager of Publications. [As. 8 or 9d.]

Like its predecessor this is a combined and curtailed report of health conditions in India during two years. In a pamphlet of 39 pages it is obviously impossible to deal with the subject in an adequate manner and in view of the extreme gravity of the health situation in India there is an urgent need for a comprehensive survey of recent developments in the public health field for the purpose of forming a true appreciation of the present position and a reliable forecast for the future.

The Report of the Health Survey and Development Committee set up by the Government of India in October 1943 to study the organization of health services in India covers part of the ground and among the recommendations contained in the report great emphasis is laid on the need for a special department under a Registrar General of Vital and Population Statistics, "to work independently of the Central Health Department but in close co-operation with it" to study vital statistics for the whole country and to "publish an annual report on the population of India, incorporating such information as is available regarding existing conditions and possible trends for the future. A similar organization for each province is recommended.

Reference to this matter has been prompted by the following statements in the first page of the present report. "Famine is of itself not a problem for health administrators since its occurrence is primarily dependent on the total

quantity of food available and facilities for its distribution. Health administrators are however vitally interested in any condition of famine since unfortunately such is invariably associated with the appearance of epidemic diseases due to causes other than mere lack of food. These remarks illustrate very clearly the radical defect that exists in the public health organizations of most countries of the world. Health depends not only on the control of infection but also on the control of the equally important preventable diseases caused by inadequate nourishment so that although health workers have not been provided with the means of controlling malnutrition they ought frankly to insist that all their efforts to prevent infectious disease must be fruitless unless nutritional disease is kept under control.

The number of deaths from famine in Bengal during the year ending April 1944 is estimated at over one million. In Madras Presidency during the same period the deaths were 176 827 in excess of the average for the previous five years and in the smaller province of Orissa the excess deaths were 52 146. The birth rate for British India has continued to fall it was 25 13 in 1944. The causes of the progressive decline during the past five years need very careful consideration and this matter is said to be receiving the attention that its importance demands.

Cholera vaccines were used on a very large scale in some provinces nearly 19 million inoculations were performed in Bengal in 1944 and in Madras there were more than 8 millions in 1943. Cholera phage was still being intensively used in Bihar in 1943 in addition to inoculation.

Few statistics are given to show the prevalence of the chief diseases but among the general statements it is interesting to note that compulsory inoculation against plague was enforced in certain areas of the Punjab and that in 1944 the Government of the United Provinces issued orders that all major irrigation and hydro-electric projects and all drainage schemes should be scrutinized by the Public Health Department before completion.

A welcome note of optimism is sounded in connexion with kala azar of which it is stated that it might easily be a considerable public health problem in the areas that it attacks but that it can be said confidently to be now being kept in check, through systematic treatment which fortunately is also an effective method of control.

More than half of the report deals in general terms with the activities of the central and provincial health departments medical research and the work of the voluntary organizations.

HERMITTE L. C. D. Venomous Marine Molluscs of the Genus *Conus*. *Trans Roy Soc Trop Med & Hyg* 1946 June v 39 No 6 485-512, 33 figs. on 5 pls. Numerous refs.]

This is an article of great importance and value in closing a serious hiatus in tropical medicine—our lack of knowledge of poisonous marine molluscs. The author deals with stings by species of *Conus* stings which are always painful often serious and sometimes fatal. A finely reproduced plate illustrates five species known to sting man and in an appendix is a list of reported cases of each. *Conus aulicus* *C. textile* (two fatal cases among these) *C. marcorus* *C. tulipa* and *C. geographus* (three fatal cases).

Dr. Hermitte gives a detailed account of a case under his own observation in the Seychelles in 1932, the first to be reported as occurring in the Indian ocean up to then all had been reported from the Western Pacific. A man 32 years of age picked up a specimen of *C. geographus* and was cleaning it when he felt a sharp sting. Turning it over he saw a 'fine sharp needle' (a radular tooth) being retracted.

"The burning sensation soon gave rise to numbness, and within a few minutes he felt his left arm tingling and gradually becoming numb. Then, feeling his head getting queer he wisely decided to regain the shore and go home. I have used the word wisely because within an hour the whole of his body was numb his sight was impaired, he had marked dizziness and nausea, he became completely paralyzed and could not move his limbs or sit up and speech was difficult. Had this occurred while he was still in the water he might well have lost his life by drowning.

After 5 or 6 hours he began to improve a little and asked to be taken to my surgery at Mont Fleuri on the main island of Mahé 3 miles distant across the lagoon.

"The accident had occurred at 9 a.m. and he was brought by pirogue (canoe) to my surgery at 6 p.m. having been carried to and from the boat in a long chair. He was still giddy and unable to stand with a feeling of general weakness in all four limbs.

On examination there was nothing to see at the site of the sting and there were no signs of hypersensitiveness such as urticaria. His knee reflexes could not be elicited but his pupils reacted normally to light and to accommodation. The pulse rate and respiration were normal there had been no respiratory difficulty at any time or any rise of temperature as far as he could tell. When examined his temperature was normal.

"These were obviously symptoms of some form of neuro-toxic poisoning. This poison paralyzes the centres of voluntary movement thus differing from the poisoning of stinging fishes which cause tetanus-like symptoms.

The author dissected specimens of the mollusc and the stages of dissection are described in minute detail and clearly shown by illustrations which will prove of much help to others desiring to carry out research into this question. With a view to finding out the nature of the poison he obtained more specimens but on their reaching England the poison had disappeared, or at least was no longer active (the specimens had been kept in alcohol). This research will probably therefore have to be carried out in the tropics on the spot. The

source of the poison seems to be the coiled tube previously regarded as the duct of the Gland of Leiblin (which is not a gland at all) Appended to the article is a list of 30-40 species of *Coxius* recorded from the Seychelles.

BOOK REVIEWS

JENSENIUS Hans *Results of Experimental Resections of the Small Intestine on Dogs. (Experimental Enteroprival Sprue.)* [Translated from Danish by HANS ANDERSEN M.D.] 275 pp 42 charts & 69 figs. on 35 pls. 1945 Copenhagen Arnold Busck Nyt Nordisk Forlag & London H K Lewis & Co Ltd 136 Gower Street

This investigation was primarily designed to elucidate the pathogenesis of pernicious anaemia. At the time of the publication of Castle's researches attention was devoted to the stomach but since 1938 when preparations of the small intestine were found to possess an anti pernicious-anaemia effect investigations on the effects of resection of this portion of the gastro-intestinal tract were also made but it was found that resection failed to produce pernicious anaemia.

The main purpose of this very thorough piece of experimental research has been to throw additional light on a symptom-complex resulting from extensive resection of the small intestine including changes in the blood picture in the absorption of intestinal contents and in the central nervous system. The relation of the symptom-complex to the clinical picture in man especially in sprue was studied with special reference to pathogenesis.

Previous clinical and experimental investigations—Most investigations appear to have been concerned with the extent of resection of the small intestine compatible with maintenance of life. This has varied from one-third to nearly the entire length, but most writers regard it as about two-thirds. On the whole children or young adults withstand this mutilation better than persons of more advanced age much depends upon the pathological condition of the bowel.

There are three possible ways in which one may try to compensate for the loss of a large portion of the small intestine—

- (1) The diet may be increased in amount especially in its caloric content
- (2) It may be rendered more absorbable, poor in fat but rich in carbohydrate
- (3) From experimental studies it appears that the unresected portion undergoes compensatory hypertrophy with resulting increase in function. Such a result has not been proved to occur in the rest of the digestive tract, i.e. the stomach and colon. Physiological studies show that the capacity for fat absorption is greater in the distal than in the proximal portion of the small intestine, which suggests that the distal portion is more essential for the maintenance of life than the proximal

The author's investigations—The animals used in these experiments have been fairly big pups about 3-4 months old. The experimental material consisted of 25 completed experiments 15 with distal & 5 with proximal resection 4 with short-circuiting of the distal part of the small intestine and 1 with distal resection of small intestine and resection of half of the colon. In all the operation involved two-thirds of the small intestine and in three instances only with distal resection was $\frac{1}{3}$ of the gut removed. Measurements must be taken at the time of operation otherwise owing to contraction, quite different values are obtained. All animals submitted to distal resection died.

provoke experiments with distal short-circuiting of the small intestine approximate those with distal resection

The clinical picture particularly after distal resection of the small intestine shows many resemblances to that observed after stomach operations but differs in the relative inconspicuousness of the skin changes and achylia in fact the clinical picture is more closely allied to sprue than to pellagra.

DE WILDFMAN E. [Directeur honoraire du Jardin botanique de l'Etat etc.]
A propos de médicaments antilépreux d'origine végétale. IV. Des *Strophanthus* et de leur utilisation en médecine. [An Account of Anti leprotic Drugs of Vegetal Origin. IV. The Use of Species of *Strophanthus* in Medicine.]
Institut Royal Colonial Belge. Section des Sciences Naturelles et Médicales.
Mémoires (Collection in-8°) 1946 v 15 No. 4 70 pp.

No IV of this series of monographs gives a comprehensive account of what is known of the numerous species of *Strophanthus* in regard to the chemical constituents and their use in medicine. This genus includes 62 species 21 of which are found in the Belgian Congo whose distribution in that area is recorded. The chemical constitution of the active ingredients varies considerably both in detail and in the quantities found in different species. Only the following three have been extensively investigated, and as the strophanthins found in them differ materially in their solubilities and activities, and as different species are recognized as official in various countries, it is necessary to add the initial of the species of plant from which each is derived when dealing with their use in medicine. Thus *Strophanthus gratus* yields strophanthin-G which is official in Germany France and the United States. *S. hispidus* yields strophanthin-H as used in a number of European and American countries and *S. kowe* provides strophanthin-K. which is used in England and many other countries. Strophanthin K. is 30 times as soluble as strophanthin-G and is less toxic it has been, therefore, much used for intravenous injection in Germany as it is excreted within 24 hours (against two days in the case of strophanthin-G) and is therefore less cumulative and toxic than the latter.

The alkaloids and glucosides are found in the greatest strength in the seeds but are also present in the roots and young bark. Their value in cardiac diseases, and as diuretics is well known. Other diseases in which information is given of the use of preparations from these plants, by the indigenous peoples of Africa and others include leprosy tetanus whooping cough, asthma, angina pectoris they are used as anaesthetics in eye and ear affections, for venereal diseases venum in the head, rheumatism, and especially for poisoned arrows, for which last purpose they were formerly cultivated in West Africa. Their use in leprosy by the Ibos (according to the late Dr Oberdoerffer) was in the form of a decoction of roots or young bark, but no evidence is recorded in this book on any results of this treatment. This work with its numerous references to the literature of strophanthins will be of great value to those interested in this important class of remedies.

ANTI RABIES TREATMENT

A DISCUSSION OF ITS VALUE IN THE LIGHT OF RECENT EXPERIMENTAL WORK.

By A J RHODES M.D. F.R.C.P. Ed

*Lecturer in Bacteriology London School of Hygiene and Tropical Medicine
(University of London)**Introduction*

Anti rabies treatment was introduced into human medicine by Louis Pasteur and his associates in Paris in 1885. Pasteur had found that the common rabies virus of the natural disease in dogs or street virus when passaged intracranially in rabbits ultimately became fixed in its properties—*virus fixe* or fixed virus. He further showed that fixed virus could be attenuated in virulence by drying an infected rabbit cord in a desiccating jar. The longer the cord was left to dry the less became the infectivity. Using cords of gradually increasing virulence Pasteur was able to treat dogs so that they withstood a subsequent test inoculation of virulent virus (PASTEUR CHAMBERLAND and ROUX 1884). Encouraged by the results in dogs Pasteur decided to try the treatment in human beings. The first case treated was a success as the patient badly bitten developed no signs of rabies (PASTEUR 1885). The treatment was at once made available in Paris and by 1886 nearly 2,500 people had been treated there (PASTEUR 1886). Pasteur's method was quickly adopted in all parts of the world, either in its original form, or after substantial modification. The most important modification was the use of chemical chiefly phenolized vaccines containing inactivated virus.

For the past 50 years or more the orthodox treatment of persons bitten by suspected rabid animals has been a course of anti rabies vaccine. It is accordingly very difficult to obtain control figures that can be used in assessing the value of anti rabies treatment.

Of recent years a considerable amount of experimental work has been performed on active immunization and it has been learnt that it is difficult to prevent rabies in experimentally infected animals if the vaccine is given after infection. It has also been shown by Webster and other American workers that a number of phenolized vaccines available for veterinary and human use have been devoid of immunizing activity (see below). For these and other reasons there has been a growing feeling that anti-rabies treatment of man as at present practised may not be as effective as it was originally believed to be. It may be said in general that French workers are convinced of the value of treatment either with attenuated or chemical vaccines. Many British and

American workers on the other hand are somewhat sceptical. A critical review on the value of anti-rabies treatment published by WEBSTER (1939 a) has brought the subject very much into prominence.

It is my object to discuss the scientific basis on which anti-rabies treatment rests with particular reference to recent experimental work. At the same time I shall try to explain some of the variable factors that make the evaluation of this treatment in human beings so difficult. Fuller references to many of the points raised will be found in an earlier publication (VAN ROOYEN and RHODES 1940).

Some Features of Rabic Infection in Man

Some properties of the rabies virus—Rabies as it occurs in nature is caused by an agent known as *virus de rage de rue* or street virus. This agent is commonly accepted as being a filterable virus although it is regarded by some as a protozoon, on account of the resemblance of the characteristic Negri inclusion body to certain protozoa. Street virus can be transmitted to laboratory animals such as monkeys rabbits guinea-pigs and mice, by peripheral or intracranial injection. After peripheral injection e.g. in the muscles virus remains viable locally for at least 4 days invades nerve fibres within 24-48 hours and spreads to the cord along these channels (HABEL, 1941 b). There is no evidence that the blood stream is concerned in the dissemination of the virus to any significant extent after peripheral injection. Virus has been recovered, and histological changes have been found most readily in the portion of central nervous system corresponding to the site inoculated (GOODPASTURE 1925 WEBSTER, 1937 1939 b KLIGLER and BERNKOFF 1943). Rabies infection can also be induced by direct intraneural injection of virus. Not only does street virus spread to the central nervous system centripetally after peripheral injection but it also spreads out centrifugally therefrom along other nerves. By the end of the incubation period virus is probably widely disseminated throughout the peripheral and central nervous systems. The term *septicæmia* is applied to this essential neurotropic property.

After intracranial inoculation of street virus in for example rabbits or guinea-pigs symptoms of rabic infection develop in about 14-20 days. If the brain of such an animal is passed intracranially in series it will be found that the incubation period becomes progressively shorter and eventually "fixed" at about 5-8 days. The virus is now known as *virus fixe* or fixed virus, and is remarkably stable in its properties. Negri inclusion bodies are not normally formed by fixed virus.

It is probable that strains of street virus may vary considerably in virulence for man. Thus certain strains found particularly in wolves and known as *renforcé* strains produce paralysis in rabbits on intracranial inoculation after a shorter incubation period than usual. Such strains may become fixed after only a few intracranial passages. At the other end of the scale is the *oulo-falo* virus of indigenous African mad-dog disease. These strains are of definitely reduced virulence for man. Although it has been suggested that *renforcé* strains are associated with unusually virulent infections, failing to respond to anti-rabies treatment the position does not seem to be sufficiently clear for a definite statement to be made on this point (PROCA and BOSES, 1940).

Fixed virus does not infect the experimental animal so readily as street virus by peripheral routes and does not show *septicæmia* to the same degree. Fixed virus is probably of considerably reduced virulence for man and may even be non-pathogenic on subcutaneous inoculation, unless large quantities are injected.

Observations that have been made on the antigenic structure of rabies viruses do not point to any marked differences between strains (see HAVENS and

MAYFIELD 1933) It would be in keeping however with the newer knowledge of viruses if future work showed strains to differ considerably one from another. In recent years such antigenic variations have been found in strains of poliomyelitis and influenza viruses for example

Sources and modes of human infection with rabies—Rabies exists in nature as an enzootic in dogs, wolves, jackals, mongooses and other animals and may be transmitted to man as it were accidentally by the bite of a rabid animal. The majority of bites treated in anti-rabies institutes throughout the world are inflicted by dogs. In India about a third of all bites are inflicted by jackals and in parts of Europe wolf bites are relatively frequent.

Dogs especially in tropical climates are liable to bite human beings apart altogether from rabies by no means all dog bites therefore even in countries where rabies is endemic are inflicted by rabid animals. It is thought that only about 50 per cent of rabid dogs actually excrete rabies virus in their saliva (WEBSTER 1942) presumably therefore only one in every two rabid dogs is actually a source of danger to persons it may bite. Wolves and jackals are said seldom to bite man unless rabid.

On occasions rabies may follow scratches or licks of rabid animals but this must be regarded as a great rarity. It is likewise most unusual to contract rabies from animals other than the four already mentioned. [This survey does not include rabies in Trinidad where the virus has been shown to be transmitted by species of vampire bat.]

Pathogenesis of human rabies—After the bite of a rabid animal virus probably remains localized in the wound for 24–48 hours and then invades nerve fibres. Virus may persist locally as it has been isolated from the scar (PACE 1903). Virus has been recovered from nerve fibres in man on various occasions (PASTEUR *et al* 1884 BARDACH 1888 ROUX 1888 1889 PACE 1903) and histological changes have been found in the nerves of the bitten limb and corresponding spinal ganglia (MARINESCO and DRAGANESCO 1932). *Septicæmia* occurs in man as in animals and virus has been isolated from nerves other than those of the bitten limb histological changes may also occur (MANOUÉLIAN 1936).

All the evidence points to the virus being disseminated in the body by nerve tracts and not to any significant extent by blood or lymph. It is held by many that the length of the incubation period is related to the distance of the wound from the spinal cord or medulla i.e. to the length of the nerve paths to be travelled by the street virus. For instance WEBSTER (1944) gives the following average incubation periods—

bites on head, face and neck—30 days

bites on upper extremity—40 days

bites on lower extremity—60 days

JOHNSON (1943) however maintains that more important factors are the amount of virus inoculated into the wound and the type of tissue bitten. The shortness of the incubation period after wounds on the head, face and neck is ascribed to the frequently severe nature of these bites and the abundance of nerve filaments available to be invaded.

It is not known how long street virus takes to reach the central nervous system from a peripherally situated bite. It is presumably present in the central nervous system for several days before the onset of symptoms and during this time centrifugal spread along nerves is taking place.

In certain circumstances it would appear that rabies virus can remain latent in the body without causing symptoms especially if anti-rabies treatment has been applied for rabies has developed after an incubation period of as long as 3 years (IYENGAR, 1935). In some cases that develop unusually late the onset of the disease may be provoked by an emotional shock (REMLINGER, 1946).

The minimal amount of virus required to infect man is not known, nor is it known if sub-infective doses inoculated in a wound in untreated persons can invade nerve paths and set up an asymptomatic infection. There is some evidence that man has an innate resistance to rabies, at any rate to the common type of canine street virus perhaps because the disease is normally spread from dog to dog, and the agent is not well adapted to invasion of human tissues.

Mortality from rabies in untreated persons.—Once rabic symptoms develop the disease is invariably fatal but only a comparatively small percentage of persons bitten by rabid animals actually develop rabies. It is extremely difficult to estimate scientifically the chances of dying of rabies following the bite of a rabid animal. Mortality figures should be based on observations made in the groups of persons bitten by known rabid animals none of the bitten being treated in any way. All the persons in question would have to be observed for a year or more to make certain that rabies did not develop. Statistics of this type are not available. Numerous observations on groups of bitten persons untreated but selected to a greater or lesser extent suggest, however that an average mortality figure is from 5 to 15 per cent this being modified by a number of factors. Thus the mortality is higher in wolf bites probably over 60 per cent especially if situated on the face. The mortality is higher in deep than in superficial wounds, in wounds on the face in multiple wounds and in wounds inflicted through bare skin (see HARVEY and MCKENDRICK, 1923). In fact the mortality from rabies in untreated persons is directly proportional to the amount of virus deposited in the wound by the biting animal and to the degree of trauma inflicted on the tissues.

Cauterization of bites of rabid animals.—The orthodox first-aid treatment of bites inflicted by rabid animals is cauterization, by the thermocautery or by strong agents such as corrosive acids. Experimental work on guinea-pigs infected by intramuscular injection has shown that application of iodine or washing with soft soap and water is as effective and does not cause scarring (SHAUGHNESSY and ZICHIS 1943). Experimental observations suggest that cauterization may itself protect against rabies, even if applied up to 24 hours later (CABOT 1889 POOR 1911 ROSENBAUM 1935). Even if promptly applied however it may fail to protect some animals (BARES and TALASESCU 1894). Presumably in such cases the cauterizing agent fails to reach virus living in pockets.

HARVEY and MCKENDRICK (1923) reported that efficient cauterization reduced the chances of developing the disease in the proportion of 4 : 3. MACKIE (1928) found it advantageous to open up wounds and wash with acriflavine. I have tried but without success, to obtain more recent figures from Pasteur Institutes relating to the value of cauterization. From what has been said it will be evident, nevertheless that cauterization has a definite protective effect. This is one of the many factors that complicate the evaluation of anti-rabies treatment as both treatments are frequently given together.

Experimental Observations on Active Immunity in Rabies.

Animals can be immunized by anti-rabies vaccines given prior to infection. Under certain circumstances they can be protected from rabies by injections of vaccine given after infection.

Type of vaccine.—Numerous preparations have been used to induce active immunity in animals the more important are as follows —

(a) Living or attenuated *virus fixe* prepared as in Pasteur's or Hoegye's method, can be used, and is an effective immunizing agent, but is not widely employed owing to the risk of death if large quantities are given. It was found that fresh living *virus fixe* used as an adjunct to the phenolized virus immunized

dogs more effectively than any other method (SHORTT *et al* 1934-5) WEBSTER (1939 *b*) using mice also found live virus vaccines to be effective immunizing agents.

(b) Chemical vaccines of various types have been much used. Phenol, chloroform, ether and formalin inactivate rabies virus if left in contact for a sufficient time and if used in adequate concentration. The process of inactivation is gradual and chemical vaccines are sometimes used at a stage when virulent virus can still be detected by animal inoculation. More usually, however, chemical vaccines are used when the virus appears to be destroyed and no sign of infection can be detected in inoculated animals. We know so little about the true biological nature of living rabies virus that it is perhaps unwise to assert that these vaccines contain 'dead' virus. All that can be said is that with products such as Semple's phenolized vaccine, tests for infectivity consistently prove negative. Whether a killed chemical vaccine contains virus in a form that may be reactivated *in vitro* is not known. It is perhaps more appropriate to refer to chemical vaccines as containing 'inactivated' virus.

Provided that the vaccine contains a sufficient quantity of virus material and that the strain is of high immunizing potency (see below) a satisfactory state of resistance can be induced in laboratory animals to a peripheral test dose and even to an intracranial injection. Injections must be given repeatedly and in large doses—for example, a monkey may require as much vaccine as is used for a human being. WEBSTER (1939 *b*) using a phenolized and a chloroformized vaccine found that mice required a dose approximately five times as great as that advocated per gramme of body weight for man. There is some evidence that chloroformized vaccines are better immunizing agents than phenolized products. Etherized and formalized vaccines are also used.

(c) Virus grown in tissue culture can be used in its live state, formalized or attenuated by ultra violet light (HODES *et al* 1937, 1940; WEBSTER, 1937, 1938; KLIGLER and BERNKOPF 1938, 1941; WEBSTER and CASALS 1941).

(d) The principle of attenuation by exposure to ultra violet light has also been extended to infected brain tissue (SANKARAN and BEER 1934-5; WEBSTER and CASALS 1940 *a*, 1941, 1942 *a*, *b*; LEVINSON *et al* 1944). It is almost certain that the virus is not completely destroyed in these vaccines as they become less effective if inactivated for too long. Such vaccines are the most potent yet produced and mice have been protected with them against 10 000 lethal (LD_{50}) doses of virus, whereas a chloroformized vaccine protected against only 1 000 lethal doses (WEBSTER and CASALS 1942 *a*).

(e) Virus inactivated by the photodynamic action of methylene blue is antigenic but probably only if some live virus remains in the preparation (GALLOWAY 1934; SHORTT and BROOKS 1933-4, 1934-5).

The strains of virus fixe used in vaccine production—Anti rabies vaccines are usually prepared from the classical Pasteur strain of *virus fixe* of which a number of 'off-shoots' are maintained in various institutes. It was found that the Pasteur strain was a more efficient antigen than *virus fixe* prepared from strains isolated in India (CUNNINGHAM *et al* 1933; SHORTT *et al* 1934, 1937).

The most important recent work in this connexion is that of HABEL (1940 *b*) who examined 31 strains of *virus fixe* of which 25 were derived from the original Pasteur strain. He made the important observation that these strains differed considerably in their ability to immunize mice. He suggested that a high immunizing potency against a heterologous test virus is not an inherent characteristic of a strain but can be altered during transfer. HAMPTIL and ROBERTS (1942) made similar observations and showed that substrains of the

same strain varied considerably, and might afford only slight protection even against the homologous virus.

With any given strain of virus *fixe* the greater the amount of virus material the greater is the immunizing capacity of the vaccine. It is therefore desirable to ensure the maximum content of virus in the brain tissue used in the vaccine, and for this purpose HABEL (1941 a) recommends that animals be inoculated with dilute rather than concentrated suspensions of passage brain.

Laboratories preparing anti-rabies vaccines should periodically test the properties of their strain of virus along the following lines (HABEL, 1940 b) specificity should be checked by a neutralization test with antiserum samples should be removed during the process of treatment with chemicals and tested for virulence in mice attenuated vaccines should be similarly tested mice should be immunized with the vaccine as ready for issue and tested by intra-cerebral injection.

Technical methods in testing active immunity—In tests for the immunizing potency of vaccines it is customary to inject the subsequent test or "challenge" dose of live virus by a rate that kills as nearly as possible all the control unvaccinated animals. Unless this dose is given intracerebrally or intraocularly it is often difficult to secure infection of more than 50-75 per cent. of controls.

Various workers using relatively ineffective vaccines, have experienced difficulty in immunizing animals sufficiently to withstand intracerebral or intraocular injections of test virus, although a peripheral injection might be resisted (see WEBSTER, 1939 a 1942). Live vaccines and the newer irradiated and chloroformized vaccines will definitely protect against a subsequent intra-cranial test dose.

In all tests of this type an accurately titrated amount of virus must be used for estimating both the immunizing dose and the "challenge dose" for this purpose it is usual to inject mice intracerebrally with falling serial tenfold dilutions using at least 6 mice per dilution. The LD_{50} or 50 per cent. mortality endpoint, which is a convenient measure of the potency of the inoculum, is then calculated. The method introduced by REED and MUENCH (1938) gives additional accuracy to this calculation.

Vaccines are now usually assayed by a mouse test such as that introduced by WEBSTER (1939 b 1940 1941) which is carried out as follows. The vaccine to be assayed is diluted 1/10 and 1/8th of the stated dose is used (representing 1/80th). A total of 32 three-week-old mice are needed. In the case of canine vaccines one dose is given intraperitoneally to each of 16 of the mice. In the case of vaccines intended for human use, the mice are given 3 to 6 injections. Three weeks after the first injection of vaccine the test and the 16 control mice are each divided into four lots and injected intracerebrally with 1 10 100 and 1,000 lethal (LD_{50}) doses. To detect a weak or immunizing effect the challenge dose can be given intramuscularly from 2 to 32 lethal doses being used. Both test and control mice are examined for 60 days.

Somewhat similar tests have been introduced by WYCKOFF (1940-1 WYCKOFF and BECK, 1940 WYCKOFF and TEXAR, 1941) and HABEL (1940 a) HABEL considered that the minimum requirement of a vaccine tested by his method was that it should protect against at least 1 000 lethal doses calculated by the 50 per cent. end-point method.

WEBSTER regarded the mouse immunity test as of considerable value in indicating the immunizing efficiency of anti-rabies vaccines, and it certainly appears to be by far the most practical and at the same time accurate, method available. REMLINGER and BAILLY (1943) however question whether mice are really suitable for such tests and suggest that they are unduly susceptible to rabid infection.

Dogs have also been used extensively in testing anti rabies vaccines and in general, a vaccine proved potent by mouse test proves effective when tested in dogs (JOHNSON and LEACH 1940 1942 LEACH and JOHNSON 1940 1942 WEBSTER and CASALS 1940 b)

It may be argued that some of these tests are too severe and in many ways the most valuable method of testing the immunizing potency of vaccines is to attempt to imitate what happens when they are used in human treatment. Thus monkeys may be challenged by street virus injected intramuscularly or, better still saliva from rabid dogs could be employed.

WEBSTER (1939 b 1940) tested a large number of commercially prepared vaccines available for sale in the U.S.A. for use in human anti-rabies treatment and for the prophylactic immunization of dogs. With the exception of one product he found that the phenolized vaccines failed to immunize mice against a subsequent intracerebral challenge dose of even one lethal dose. chloroformized preparations were somewhat more effective. With dogs chloroformized vaccines were found to give protection if the challenge dose was given intramuscularly, the phenolized vaccines studied in this work being valueless (see also WEBSTER and CASALS 1940 b 1942 a LEACH and JOHNSON 1940)

A considerable amount of work has been carried out on the mass prophylactic vaccination of dogs as a means of controlling rabies and it has been customary to give only one injection. The observations of Webster just quoted showed however that the bulk of canine vaccines sold for the purpose were quite unable to confer a significant degree of immunity after a single injection. If large or repeated doses of potent phenolized or chloroformized vaccines are used a high degree of immunity can be acquired and the irradiated type of vaccine is even more potent.

Anti-rabies treatment of experimentally infected animals—As has been seen above, it is perfectly possible to immunize animals by injections of potent vaccines containing live or inactivated virus given prior to the test dose of living virus. Immunity of this type has little direct bearing on anti-rabies treatment of man however where the course of vaccine has to be administered after the infection has been initiated. Accordingly a number of workers have tried to prevent rabies from developing in animals infected by peripheral routes by giving courses of anti rabies vaccine after infection and in general, have found it difficult to achieve protection (for references see WEBSTER 1939 a 1942)

For example extensive work, chiefly with monkeys was carried out over a period of years in India using chemical vaccines. Although some degree of protection was shown the results were disappointing as it was not possible to protect as many as 50 per cent of animals, if the treatment was given after infection was initiated (CUNNINGHAM and MALONE 1930 CUNNINGHAM *et al* 1933 SHORTT *et al* 1934 1934-5 COVELL *et al* 1936-7)

Certain workers have been more successful. FERMI (1908) for instance treated rats with large doses of vaccine after infection and secured a significant degree of protection. More recently HABEL (1940 a) working with guinea pigs infected intramuscularly was able to protect 16/27 by a series of 21 daily injections of 0.5 cc. phenolized vaccine. 4/3 controls developed rabies. It may be noted that the dose of vaccine used was very large as compared with the dose recommended for human treatment. In another series of experiments mice infected intramuscularly with street virus were not protected by subsequent injections of phenolized virus although chloroformized vaccines occasionally protected when five doses of an irradiated vaccine were given rabies was prevented in most instances (WEBSTER 1939 b WEBSTER and CASALS 1942 a)

It may be concluded therefore that it is difficult to protect laboratory animals by anti-rabies treatment given after infection. Large doses of chloroformized phenolized and particularly the potent irradiated vaccine may, however, secure protection in the smaller laboratory animals. A powerfully protective effect of vaccines in infected monkeys has yet to be shown.

Serum therapy in experimental rabies—Virus-neutralizing antibodies develop in the blood of infected animals and human beings. Powerfully rabidicidal sera can be produced by hyperimmunization of animals for instance in sheep or rabbits by inoculation of phenolized virus followed by the living agent (SHOKTT *et al* 1934-5 HABEL, 1940 & 1945).

A number of workers have shown that rabies can be prevented in experimental animals by injections of antiserum given just before or just after injection of the virus. For example antiserum can protect mice when injected before an intracerebral test dose, and is effective even up to 4 days later (HOYT *et al.*, 1936 HOYT and GURLEY 1937-8 1938). Other recent workers have also demonstrated the protective effect of serum (*e.g.* PROCA *et al.* 1935 YEN 1942 FRIEDEMANN *et al* 1944). Special mention must be made of the observations of HABEL (1945) who worked with guinea-pigs and mice. He found that serum was most effective when given intramuscularly at the site of inoculation and immediately after the virus. The treatment of infected animals with serum gave consistently better results than vaccination alone. The best results were achieved when serum was followed by vaccine treatment 6 days after the administration of the serum.

Mode of operation of anti-rabies treatment in experimental infections—We have seen that courses of potent anti-rabies vaccine given before and in certain circumstances after infection can protect the experimental animal from rabid infection. What immunity mechanisms are involved? Is there a different explanation for immunity produced by live virus, by "killed" virus, and irradiated virus which is probably attenuated and not actually destroyed?

When the vaccines are given before infection there is ample time for the body to build up protective mechanisms in the ordinary way, and in the active immunity acquired by this method there are probably two main mechanisms concerned. Serum virus-neutralizing antibodies presumably play some rôle, although they cannot always be detected in animals which are nevertheless resistant to infection. The beneficial effects of rabies antiserum on experimental infection presumably due to destruction of virus at the site of inoculation, should be recalled. Secondly the immune tissues appear to exert some direct virus-neutralizing effect (KUBES and GALLIA, 1944). It has been shown that when virus is introduced into the tissues of an actively immunized animal it disappears from the site of inoculation more quickly than in a normal animal and probably does not invade nerve tissue at all (HABEL, 1941 & KLIGLER and BERNKOFF 1943). The reticulo-endothelial system may also be concerned as the immune state is said to be abolished by blockade with Indian ink (LOEFFLER and SCHWENBURG 1933-4).

It is difficult to see how this more or less direct neutralization of virus by serum or tissue can play a part in the immunity acquired by post-infection treatment. The course of injections cannot stimulate the production of significant amounts of antibody for several days, and by this time the invading street virus must have progressed far along nerve tracts *en route* to the central nervous system, and be no longer accessible to circulating antibodies. Two alternative suggestions can be advanced to account for the resistance undoubtedly acquired under certain circumstances by animals subjected to anti-rabies treatment after infection—

(1) It may be assumed that the infecting virus does in fact invade and pass along nerve tracts. This process takes time and before the virus has reached

the central nervous system the course of injections of vaccine has rendered the normally susceptible nerve cells resistant to invasion. Serum antibody may play some part though probably small in this neutralization. It may neutralize any virus remaining in the wound but cannot affect that in nerve tracts. The antigen in the vaccine injected subcutaneously must be absorbed by the lymph or blood so that it can reach the nervous system ahead of the street virus. If the vaccine contains live virus, presumably some particles of *virus fixe* may invade nerve fibres and spread to the central nervous system by this route. As large quantities of vaccine are always given it is certain that the bulk of the virus must be absorbed from the site of injection by the lymph or blood stream.

The immunity according to this suggestion must be chiefly dependent upon an acquired resistance of the nerve cells.

(2) Of recent years much has been learned about a phenomenon of virus immunity known as interference. Thus it has been shown that under certain conditions the presence of one virus may interfere with and prevent the growth of a second usually closely related virus. For example mixtures of Rift Valley fever and yellow fever viruses when inoculated in the monkey did not prove so pathogenic as yellow fever virus alone (FINDLAY and MACCALLUM, 1937).

HENLE and HENLE have carried out important studies using influenza virus exposed to ultraviolet irradiation as an interfering agent (1944 a & b 1945 a & b). Thus in experiments in eggs, they showed that virus almost completely inactivated by ultra violet light was capable of preventing the multiplication of active virus introduced into the same egg some hours later or a short time earlier. Although virus might be prevented from multiplication by the interfering dose it was not actually destroyed. The interfering agents in these experiments were found to be the elementary bodies themselves.

For interference to occur in virus infections the interfering agent must, apparently, be living or else attenuated as by ultraviolet light. It is improbable that a true interfering effect can be produced by an inert dead virus.

When injections of live or irradiated vaccine are given after infection it is probable that the bulk of the fixed virus in the vaccine is absorbed into the blood and reaches the central nervous system. Here the virus particles occupy susceptible nerve cells and may produce some histological changes (see below). When the street virus ascending slowly along nerve tracts reaches the central nervous system it finds the cells it would normally infect already occupied. Hence no infection can be initiated. It is probable that the street virus is not actually destroyed by the interfering agent, and may remain latent for a period, perhaps to give rise to symptoms of rabies after a long interval.

It is difficult to see how killed particles in for example Semple's phenolized vaccine can act as interfering agents unless, as suggested above some reactivation occurs in the tissues.

In support of the suggestion that the interference phenomenon may operate is the fact that definite lesions occur in the central nervous system of animals vaccinated by the Pasteur method (NICOLAU *et al.*, 1931 CRUVEILHIER *et al.* 1935). These lesions have been attributed to a mild infection by the attenuated virus. Thus there is some cellular infiltration and satellitosis of nerve cells. Further LÉPINE and SAUTTER (1938) found nuclear inclusions in brain cells after vaccination with phenolized virus and attributed these to the presence of living virus in their vaccine.

At this point it may be of interest to refer to certain work carried out with bacteriophage which has recently been reviewed by DELBRICK (1946). Although the precise biological position of this agent is obscure it is evident that it has many properties resembling those of animal viruses. When attempts

SUMMARY OF RECENT ABSTRACTS *

IN. LEPROSY

Epidemiology

JONX (p. 389) contributes an interesting note on a small focus of leprosy which existed up to 1927 in Switzerland. Two groups of people were involved, and in each group there was a strong family history of the disease.

DHARMENDRA and SANTRA (p. 738) review the results of leprosy surveys made by the latter in various parts of India. The incidence varies considerably from 0.17 to 6.64 per cent of the population in different parts; the incidence of lepromatous disease varies from 0.1 to 0.98 per cent, providing from 5 to 62 per cent of the total cases. A high total incidence is usually associated with a high incidence in children and of lepromatous cases. The proportion of infected children varies greatly. The authors make the point that in some areas patients with advanced disease are isolated in their own homes or in huts outside the villages and that where such measures are customary a high lepromatous rate tends to be associated with a low gross incidence and a low child rate. This indicates that such measures help to control infection; the tendency should be encouraged.

In the Annual Report of the Indian Council of B.E.L.R.A. for 1944 (p. 1005) the same point is made: that a comparatively high lepromatous rate may be accompanied by low gross incidence and a low child rate in areas where some kind of isolation is practised.

In the annual report of the Madras Provincial Council of B.E.L.R.A. (p. 290) it is stated that village surveys have shown a gross incidence rate of 2.47 per cent and a child rate of 2.68 per cent; these are very high. There are great variations in the infectivity rates in different villages. A reduction in child infections has followed night segregation of infective patients in villages, by which means contact with susceptible children is reduced. It is estimated that 5 000 to 7 000 persons with leprosy are living in Madras city of whom some 10 per cent are probably infective.

An account of leprosy in the Tehri Garhwal State, United Provinces, India is given by SANTRA (p. 393). A survey showed an incidence of 2 per cent, and a high proportion of cases are infective. SHAMA RAO (pp. 393-1005) reports on leprosy surveys in Hyderabad, where incidence varies from 0.24 to 0.36 per cent., and where 31 to 43 per cent. of the cases found were lepromatous.

MUIR (p. 390) has paid return visits to Antigua, St. Kitts and Nevis and Jamaica and reports on the progress made in relation to leprosy since his first visit. These reports are primarily of local interest. VAN DER SAR (p. 391) gives an account of the history of leprosy in the Dutch West Indies.

Leprosy surveys in Bolivia have shown an incidence rate of 0.07 per cent. SUAREZ (p. 813) shows that the foci are active, stationary or in the process of becoming extinct. Of the cases found the great majority were in males of middle age. Various measures are being taken for treatment and contact examination.

MUIR (p. 1004) has given an account of the past work of B.E.L.R.A. and outlines plans for future work in the Colonies.

Aetiology

DAVISON (p. 295) has found *Mycobacterium leprae* in scrapings from the nasal mucosa in cases of nerve leprosy but only rarely in material from incision of a macule.

The information from which this series of summaries has been compiled is given in the abstracts which have appeared in the *Tropical Diseases Bulletin* 1945, v. 42. References to the abstracts are given under the names of the authors quoted and the page on which the abstracts are printed.

He makes the point that smears should be stained for 20 minutes in warm fuchsin and decolourized for 20 minutes in 5 per cent sulphuric acid. If these times are reduced there is a danger that diphtheroids may retain the stain and be mistaken for *Mycobacterium leprae*. By using a triple stain ALEXANDER JACKSON (p 899) has demonstrated non acid fast forms of *Mycobacterium leprae* in nasal smears and in skin of leprosy patients. Zoogloal and spore-like forms were also apparently demonstrated.

DHARMENDRA and MUKHERJI (p 900) have failed to infect splenectomized monkeys by intraperitoneal injection of clippings from the skin of lepromatous patients. They have therefore not confirmed previous work by others who have claimed success by this method.

DE SOUZA ARAUJO (p 132) has cultivated strains of acid fast bacilli from groups of ticks of various species which had been allowed to feed on leprosy patients and which had subsequently been triturated and inoculated on to Loewenstein's medium. He considers these pigmented organisms to be *Mycobacterium leprae* and from them has prepared leprolins for use in intradermal tests. These have been compared with lepromin in a series of tests carried out by MARIANO (p 133) there was considerable difference in the results.

DE SOUZA ARAUJO (p 1006) has infected white rats by infecting them subcutaneously with emulsions of the glands of a patient with leprosy which were rich in *Mycobacterium leprae*. From some of the organs of the rats he succeeded in cultivating chromogenic acid fast organisms. He (p 1006) has also cultivated on Loewenstein medium acid fast organisms from pus taken from a fluctuating leprotic lesion of a boy. When these cultures were injected into animals they caused abscesses in the axilla peritoneum and elsewhere but smears from the viscera were negative.

GRAU TRIANA (p 212) claims to have cultivated leprosy bacilli on modified Petraghani's medium to which at the time of sowing 10 drops of a solution of oxidase from potato with or without 10 drops of a solution of ferrous sulphate are added. The reasoning which led to this method is that in media sterilized by heat such ferments are destroyed but that the tubercle bacillus can grow because it supplies its own ferments whereas the leprosy bacillus is deficient in oxidase. The author states that colonies begin to appear in 5-7 days. In a second paper GRAU TRIANA *et al* (p 213) give details of several media used on these lines.

TROUT (p 900) has cultivated an acid fast organism from lepromata on a Difco agar medium over which CO₂ was passed during incubation.

IGNACIO CHALA and LLERAS RESTREPO (p 568) have studied 6 strains of acid-fast bacilli isolated from leprosy lesions in man by inoculation into animals and have made a detailed account of the lesions provoked. Complement fixation reactions were tested with certain well-known strains and in a minority of cases positive results were obtained.

Pathology and Clinical Findings

PARMAKSON (p 295) has made careful histological examinations of the skin in various types of leprosy. He concludes that active skin lesions in nerve leprosy are characterized by tuberculoid changes but that these changes do not occur in lepromatous leprosy. In clinical nerve leprosy lepromatous changes are not found. If a change from one type to another occurs the typical appearances of the one disappear before those of the other arise. The Mitsuda reaction is usually negative in lepromatous leprosy and positive in nerve leprosy.

CERRUTI (p 567) made a detailed study of biopsy material taken from the nasal septa in leprosy and points out that some of the pathological changes may be found in patients who clinically appear to be normal. This kind

of examination may therefore be useful and important in early diagnosis and especially in contacts.

MESTRE MIYARES (p. 43) classifies leprosy as lepromatous, tuberculoid or non specific. The first type is infective, the second not, and the third may remain true to its form (the neural type) or may pass to either of the others.

DE SOUZA ARAUJO (p. 1010) on the other hand, thinks that the division of leprosy into lepromatous, tuberculoid and macular types is artificial and that all forms are mixed. By examining the cutaneous lymph in tuberculoid cases he has found small granules and coccobacillary forms of the organism and thinks that relapses in apparently burned-out cases are due to development of these forms.

IBARRA PEREZ and GONZALEZ PRENDES (p. 1009) note that in children separated from leprosy parents there is usually a silent interval, lasting up to 5 years before signs of leprosy appear in them. They have analysed the initial lesions seen in a large number of cases of leprosy. These were macular in 37.9 per cent., but areas of anaesthesia, infiltration of the ears, systemic disturbance with fever and rhinitis were the first signs in smaller percentages. Most of these early lesions were on uncovered parts of the skin. The authors think that the nose is not the portal of entry, but rather the portal of exit of the organisms. Examinations of the placental tissues, umbilical cord blood from the cord and from the infants themselves in a series of 16 newly born children of leprosy mothers were made by TRESPALACIOS and JOVER (p. 212) with completely negative results for leprosy bacilli.

DE SOUZA (p. 567) reports a case of leprosy in which ptosis, enophthalmia and myosis were present, possibly due to leprosy. The syndrome is well known but is usually the result of other conditions.

ARGUELLES CASALS (p. 568) describes a case in which exquisite tenderness of the finger tips and nails was present along with leprosy. He does not argue that leprosy was necessarily the cause of this condition.

DEGOTTE (p. 295) has investigated the question of the infectivity of neural leprosy in the pygmies of the Belgian Congo. On the whole he thinks that such patients are at times infective.

Changes in the euglobulin tyrosin and the albumin-globulin ratios in leprosy are attributed by ROSS (p. 297) to hepatic dysfunction and to liver damage.

Lepromin. Other Tests.

At the Leprosy Research Department, School of Tropical Medicine, Calcutta (p. 739) further research has been done by DHARMENDRA on the antigens of the leprosy bacillus and other acid-fast organisms. The acid-soluble fraction of all these is active, giving positive reactions in neural leprosy and negative reactions in lepromatous disease. The fact that one of the tested organisms (Hedrowsky's) is easily cultivated will greatly simplify the production of an antigen of value in prognosis.

BECHTOLD *et al.* (p. 800) have tested with lepromin persons (in New York) who have never been in contact with leprosy. Some positive results, both delayed and early, were given. They found that the early reactions were given in 35 of 36 tested, by people positive to tuberculin and think that infection with the tubercle bacillus may account for this result.

ROTHBERG (p. 568) produces convincing evidence to show that leprosy patients negative or weakly positive to lepromin are much more likely to develop serious reactivation of the disease than those who give strongly positive results. If this fact were appreciated, the preventive medical services could concentrate more actively on following up the negative and weak reactors, who are prone to relapses of infective type. FERNANDEZ (p. 471) makes the point that, in an infected person, a positive reaction to lepromin indicates good resistance and a

good prognosis. A negative test in such persons is an indication that careful observation is needed, and it is advisable to start treatment. prognosis should be guarded. The same author (p 297) has found that non-lepromatous persons can be rendered sensitive to lepromin by intradermal injection of suspensions of *Mycobacterium leprae* or of tubercle bacilli. The early reaction to lepromin (due to the protein fraction of *Mycobacterium leprae* and to be distinguished from the late Mitsuda reaction) can be attributed to previous sensitization by leprosy or tubercle bacilli.

MOX and BASOMBRO (p 1012) have continued their work on lepromin and 2-4 dinitrochlorobenzene and now report that intradermal injection of each of these substances gives reactions which in the majority of cases are remarkably concordant. There are few cases in which they are contradictory. The injections may provide early or late reactions and these tend to be negative in lepromatous leprosy and positive in tuberculoid and non-characteristic cases.

DE SOUZA ARAUJO and MIRANDA (p 1007) found that ticks fed on leprosy patients may take up leprosy bacilli and that from these ticks acid fast organisms can be cultivated. Similar findings are recorded by DE SOUZA ARAUJO (p 1007, 1008) in the case of triatomid bugs, certain mosquitoes, sandflies, simuliid flies and leeches but not in the case of *Cimex lectularius*. The same author (p 1008) has cultivated the acid fast organisms taken up by these insects and has obtained 7 cultures, one from the original patient, the remainder from ticks and triatomid bugs. He and his colleagues (p 1009) have attempted to transmit leprosy to man by the bite of infected triatomid bugs but the results were indefinite [partly, perhaps, because the persons whom it was intended to infect were burned-out leprosy patients].

A somewhat similar experiment was carried out by DE OLIVEIRA CASTRO and MARIANO (p 1009) but with mosquitoes instead of bugs. After the infected mosquitoes had bitten patients with burned-out leprosy, acid fast organisms were found in the connective tissue spaces near the bite but there remains the possibility that they were there before the experiment was made.

DE SOUZA ARAUJO (p 1010) describes his method of preparing lepromin from lepromata by emulsification and addition of phenol. MARIANO (p 1010) has tested 5 of the lepromins prepared by de Souza Araujo, three of them were derived from cultures of acid fast organisms from ticks (see above). He compared the results of tests with these lepromins with results given by lepromin and found a considerable degree of agreement though there was some variation between the different lepromins. MIRANDA (p 1011) has done similar work with similar results. In general, these lepromins tend to give negative reactions in lepromatous cases and positive reactions in nerve leprosy.

BALAGANGADHARAN (p 739) brings evidence which supports the view that the Kahn reaction is quite often positive in leprosy in the absence of syphilis. ECKLES and ROSS (p 297) state that the Mazzini flocculation slide test though not so sensitive in leprosy as the Kolmer and Kahn tests has the advantage of greater simplicity.

Treatment

At a Conference held at the Pretoria Leper Institution (p 292) DREWES referred to the value of rest and good food in the treatment of leprosy. DAVISON defined the criteria of cure which should be applied before patients are discharged from hospital. He also discussed the kind of leprosy institution which would be suitable for South Africa and other countries with a similar incidence of leprosy and the question of compulsory segregation of which he approves in certain conditions. MOISER showed that conjugal infection in Southern Rhodesia was low 1.57 per cent and referred to the possible transmission of the disease by cockroaches. THORNTON noted that at the institution for leprosy in the

Transkei 27.3 per cent of patients had been discharged during the past 10 years in some of these recrudescence had occurred.

No benefit from the use of pooled plasma transfusion was noted by FAGET and POGGE (p. 297) in the treatment of leprosy. It was thought that this treatment might prove valuable in the hypoproteinaemia and nephritis of leprosy but the results were disappointing.

SEAMA RAO (p. 393) describes a simplified method of preparing iodized *H. duocarpus* oil for details the original abstract should be consulted. DEGOTTE (p. 394) could not obtain chaulmoogra oil in the Belgian Congo during the war and experimented with an oil obtained from a common plant containing citronella. The results of treatment with this oil were reasonably satisfactory. ROIG and RODRIGUEZ DE LA CRUZ (p. 214) discuss the oils of the Cuban *Flacour* *ciacese*.

COT LESMES (p. 44) has used diphtheria toxoid in the treatment of leprosy and reports favourably on the results especially in lepromatous cases. This finding is in contrast with much of the more recent work on the same lines and with the opinion of TIAN (p. 45) who thinks that this form of treatment shows little promise. He considers leprosy to be curable by general measures of improvement of health and by the use of chaulmoogra oil in high dosage.

DOS SANTOS NEVES (p. 472) has treated a few patients with vitamin A and a chologue with satisfactory results.

Penicillin is apparently useless in the treatment of leprosy (FAGET and POGGE p. 646).

ALLER ATUCHA (p. 902) writes strongly in favour of local applications of sulphathiazole in leprosy the drug either as a 15 per cent. jelly or a 10 per cent suspension in oil or a 15 per cent. watery emulsion is applied to the skin after it has been scraped, or to ulcers. Lesions of the eye may also be treated with these preparations and treatment with injected sulphathiazole along with injections of chaulmoogra oil, is apparently useful for generalized lesions.

In trials of sulphanilamide given by injection in rat leprosy CHORINE and CHARAUD (p. 298) have failed to find evidence of any effective therapeutic action but local application of sulphanilamide in the treatment of ulcers and burns in leprosy and treatment of the ocular lesions (keratitis, irido-cyclitis, etc.) with a preparation of sulphanilamide have given encouraging results in the hands of CHORINE (pp. 298-1013).

AMENDOLA (p. 901) has had satisfactory results, in ocular leprosy from extirpation of the lachrymal gland. This is not surprising if the glands themselves are infected, but the author has also seen benefit even when the glands showed no evidence of disease.

SAGHER (p. 740) has used Grenz rays in the disfiguring lesions of leprosy with some success.

AMENDOLA (p. 901) discusses tracheotomy in leprosy pointing out that it is not usually an emergency operation. The low operation is to be preferred but there may form a thick muco-membranous exudate below the cannula which is difficult to remove and which may necessitate a second urgent operation for its removal.

Arguing that the cause of perforating ulcer of the foot in leprosy is occasioned only by the loss of sensation and consequent inattention to any wound, SILVEIRA (p. 473) states that ordinary treatment is effective. KIRKALDY WILLIS (p. 740) has performed arterial sympathectomy, to promote healing of an ulcer of the foot in a leprosy patient.

Institutions Control.

BURGESS (p. 298) estimates that throughout the world no less than 15,000,000 people are affected by leprosy either directly by the disease or because they are

dependants of infected persons. He proposes a world federation of communities of infected persons which should be largely self-supporting through organized employment and in which provision should be made for the families infected or not. [The conception of communities in which these people should not be penalized because of a disease for which they are not responsible is growing. These organized communities would not only offer a solution to the troubles of the infected, they would also help perhaps more than anything else to eradicate the disease but they should be attractive.]

DAVEY (p 1013) reports on the work done in the Owerri Province of Nigeria where in a population of 2 000 000 there are probably 75 000 persons suffering from leprosy. Some 18 500 patients have been brought within the scope of the leprosy work directed from the great leper colony and they are cared for either in the central settlement or in the 27 special villages or at over 40 out-patient clinics. Repeated surveys are made and developing cases are discovered and treated while they are in a stage at which treatment is most likely to succeed. There are 20 leprosy inspectors at work in different parts of the Province and their duties include the examination of contacts of infective persons. Already in six areas and with the cordial cooperation of the people themselves practically all infective patients are isolated and receive treatment. In these areas progressive diminution of the incidence of leprosy may be expected. The work has largely been financed by B.E.L.R.A. but the Nigerian Government has now taken it over with the object of extending its scope.

The work of the Oji River leprosy settlement in Nigeria has progressed in spite of the war and MONEY (p 392) states that in 1943 there were 1 187 in-patients. There is a special compound for children. In the surrounding country there are several out-patient clinics at which treatment is given. In the whole Province there are 20 000-25 000 active cases of which 3 000-5 000 are infective. Many of these are segregated in leprosy villages but many more are isolated in their homes.

In the Belgian Congo compulsory segregation of leprosy patients is not advised, but ZANETTI (p 741) states that numerous agricultural villages are being organized, each to provide for 300-400 cases. These are visited each week by a medical officer. Isolation in these villages is more or less voluntary but some mild pressure is applied.

DEKSHAM (p 392) reports on a settlement recently started in Northern Rhodesia.

COCHRANE (p 291) discusses the whole question of leprosy control especially in relation to the Madras Presidency. He advocates surveys of the different communities, night segregation of infective persons in their homes and villages to lessen the infection of children. Institutions should be provided by all municipalities and special sanatoria for children because they cannot be isolated at home. Child contacts should be examined periodically. The Madras Public Health Act is being modified in this sense. No success can be expected unless a well qualified medical officer is placed in charge of the campaign in each province.

SEN (p 1014) refers to a home for leprosy patients which has been founded in India and which is financed partly by private subscriptions and partly by grants from local authorities. It is the first of its kind to be supported in this way by the people themselves. He remarks that many of the inmates had been driven from their homes by their relatives. The home now contains some 300 patients. If similar undertakings were initiated elsewhere some solution of the problem of begging lepers in India might be found.

AUSTIN (p 736) has written an account of the Central Leper Hospital Makogai Fiji. This is very well equipped for treatment and the patients are also employed in certain industries. In recent years 40 patients per annum

have been discharged with only 10 per cent. of relapses. Isolation is compulsory but the conditions are so favourable for the inmates that compulsion is regarded as successful. An account of the work of this hospital during 1943 is given by the same author (p. 294) this cannot further be summarized. This institution is very progressive.

HOPKINS and FAGET (p. 737) have analysed the cases admitted to the National Leprosarium at Carville between 1928 and 1944. Admissions of patients from Texas have increased, and the disease is still endemic in some of the southern States and Mexico though it is declining in the foci in Massachusetts and Minnesota. There are still many white patients some of whom are soldiers infected during various wars. A family history of leprosy is not uncommon where it can be obtained, but conjugal infection is rare. The authors believe that the Kohner and Kahn tests may be positive in leprosy in the absence of syphilis. The duration of cases from admission to death varied from 9.3 years (lepromatous) to 14.5 years (neural). 145 of the 723 patients were discharged with arrested disease and only 16 relapsed. Most of the discharged patients had neural or tuberculous leprosy. Most of the deaths were due to nephritis, tuberculosis or leprosy.

WHARTON (p. 737) describes the leprosy hospital at Mahanua, British Guiana. From this institution a programme of contact examination is being conducted. As a result of examination of children a number of early cases have been detected.

SLOAN (p. 296) claims that the policy of compulsory segregation has been effective in Hawaii and quotes the decline in incidence since 1890 in support of his contention.

Rat Leprosy

FIELDING (p. 903) has made a careful study of rat leprosy. He has demonstrated heavy infections of the stomach, and related these to the heavy excretion of leprosy bacilli in the faeces. Repeated inoculation of the skin with emulsions of rat leprosy bacilli is capable of causing extensive invasion of the skin and the bacilli have been found in those parts of the skin which come into contact with the ground, and therefore potentially with infective material. This creates a link between soil contamination and dissemination of the disease. The results of Fielding's work also indicate that rat leprosy bacilli from faeces, urine and primary ulcers are more virulent than those from granulomata and ulcers of long standing. For the production of superficial lesions there must be repeated inoculation, or injection of the organisms and the use of bacilli of high virulence. In natural conditions infection is doubtless due to repeated contact with soil infected by faeces containing the organisms but may also be carried by rat lice. Hookworm larvae can also introduce the bacilli, but faecal organisms introduced by the mouth failed to infect.

LINARES (p. 1014) discusses possible routes of infection in rat leprosy and shows that he has been able to infect fowls by feeding them on rat leprosy material or by injecting it and pigeons by injection.

DHARMENDRA and MUKHERJI (p. 903) found that sulphapyridine given by the mouth, had no effect on rat leprosy.

Charles Wilcocks

MALARIA.

BIRRELL N. V. A Case of Indigenous Malaria in Northern Ireland. *Brit Med J* 1946 Apr 27 649-50

A member of the W R N S with *P vivax* malaria was admitted to hospital in Londonderry on July 16th 1945. The author advances sound reasons for his belief that infection had been contracted locally. *A maculipennis* [variety not named] was found breeding in the locality, there were numerous cases of malaria under treatment among members of the Services and the spring of 1945 had been unusually mild. Norman White

COLLINS R. H. Rural Malaria its Epidemiology and Prevention. A Study *Turkische Ztschr f Hyg u Exper Biol* Ankara. 1941 v 2 No 2 17-28
Turkish version 5-16

The author reports an outbreak of malaria in Sincanli, Turkey in a group of refugees who entered the area. *Anopheles maculipennis typicus* and 4 *superpictus* were present. All three types of parasite were found, *P. malariae* being relatively common in the small series recorded. Charles Wilcocks

DUKHANINA N. N. [Carriers of *Plasmodium vivax* in the North under Mass Chemoprophylaxis.] *Med Parasit & Parasitic Dis* Moscow 1945 v 14 No 5 63-76 1 fig [In Russian.]

Observations were made on the carrier-state in malaria (*P. vivax*) among the population of the Archangel Province in northern U.S.S.R. [61-62° N Lat.] The special objects of the investigation—apart from the general characteristics of the carrier-state in the north—were the conditions under which infected persons become carriers the effect of treatment causes of repeated carriage and density of parasites in carriers as compared with that in persons with clinical symptoms.

In the village (Telegovo) selected for this investigation the highest percentage of carriers among the persons examined was 9 per cent. in 1939 the lowest 0.5 per cent in 1940 while in 1941 there was not a single carrier the decline being correlated with an amelioration of the epidemiological position. Carriers were found both among persons affected with malaria in the preceding and in the current year (12.6 per cent.) and among those who had no malaria but were equally exposed to infection (4.5 per cent.) In 73 per cent of cases carriers were detected in the pre-epidemic period, and only 27 per cent in the epidemic period. Among persons who had undergone drug prophylaxis parasite-carriers made up 42-44 per cent. of the total number of cases of malaria. As a rule the carriers were persons who had received insufficient drug treatment. The number of parasites in the blood of carriers is considerably lower than in acute cases in 90 per cent of cases not exceeding one parasite per field of the microscope. C. A. Hoare

SOUTH AFRICA UNION OF Malaria Areas in the Union of South Africa. A Map of the Malarial Survey by the Department of Public Health of the Union (in collaboration, in the case of Swaziland with the Swaziland Administration) 1938. 1941 Pretoria Govt. Printer

The scale of this map is 15.77 miles to the inch. On it are shown four areas —
A In which the risk of infection is continuous
B In which it is serious and in which epidemics occur during summer
C In which a summer epidemic occurs each year but of milder type
D In which epidemics occur occasionally

Area A is found only in one district of the east coast near the border of Mozambique. Area B covers the north and east of the Union with Area C to the south and west of Area B. Area D lies again to the south and west of Area C, and reaches Pretoria Witbank, Newcastle and Durban. The remainder (and greater part) of the Union is apparently not affected by malaria.

It is explained that the areas are only approximately correct. They are shown in 4 colours and are very clearly marked. This is a useful map for the malarologist: it measures some 3 ft. 8 in. by 3 ft. No price is quoted: the map was produced for official purposes.

MCARTHUR J. N. Malaria Transmission in Borneo. *Lancet* 1946 July 27 117-18.

Before 1939 it was assumed that the epidemiology of malaria in Borneo was similar to that in Malaya and that the disease was carried mainly by *Anopheles maculatus*. Epidemiological survey in 1939 to some extent supported this assumption except that one village was inexplicably relatively free from the disease despite the presence of abundant *A. maculatus*. An investigation, to explain this revealed a general scarcity of *A. maculatus* in malarious villages and later work showed that this mosquito fed predominantly on animal blood and was therefore unlikely to be a vector. Further work showed that only one species *A. leucosphyrus* had a preference for human blood. It was recovered in numbers from human-bait traps and on dissection 25 specimens were found to be positive [the number dissected, and the numbers with sporozoites and oocysts are not stated]. 2 700 dissections of other species including *A. maculatus* were negative.

A. leucosphyrus appears to be the most widely distributed mosquito in Borneo. It enters houses after midnight, feeds on the sleeping inhabitants and leaves before dawn so that it is rare in daytime catches. It breeds entirely in the jungle and is easily controlled by localized jungle clearing around its breeding places and this is probably the simplest method of preventing malaria in Borneo. In contrast to Malaya where the land becomes malarious after the clearing of jungle and the consequent introduction of *A. maculatus*.

The author concludes that though *A. leucosphyrus* is often said to be harmless yet wherever it has been studied in adequate numbers it has always been found positive on dissection and that it may prove to have much more relation to malaria in other parts of the world than has hitherto been supposed, its presence being masked by its elusiveness and its virulence by the presence of some other much more easily captured and incriminated mosquito.

G. Macdonald.

Downs W G & Pittendrigh C S Bromeliad Malaria in Trinidad, British West Indies. *Amer J Trop Med* 1948 Jan v 28 No 1 47-66 7 figs [20 refs]

This is an admirably concise and complete account of the complicated problems attendant upon the control of malaria transmitted by bromeliad breeding anophelines of the subgenus *Kerteszia* in Trinidad. The history of investigations on bromeliad malaria is outlined. In 1935 DE VERTEUIL [this *Bulletin* Supplement 1938 v 33 281] published a detailed malaria survey of cacao-growing areas of Trinidad and concluded that the high malaria incidence and mortality of these areas was due to *A. bellator*. This conclusion was subsequently fully confirmed by ROZEBOOM and LAIRD [this *Bulletin* 1942 v 39 664] and by DOWNS GILLETTE and SHANON [this *Bulletin* 1944 v 41 445].

Throughout a large part of the centre of Trinidad forest has been replaced by plantations of *Theobroma cacao* (cocoa). The cacao trees are protected by tall regularly interplanted shade trees immortelles *Erythrina glauca* and *E. micropteryx*. The plantations as a whole constitute an extensive artificial forest which supports a large human population. The immortal trees are very heavily parasitized by bromeliads. Thirty four species of bromeliads have been found on these shade trees of Trinidad cacao estates five of these species are universal being found on almost every tree. On 50 sample trees the average number of bromeliads per tree was 66. The number of immortal trees to the acre varies from 11 (in abandoned areas) to 64. The different bromeliads are by no means of equal value as host plants of *A. bellator* there is a host plant selection on the part of this anopheline. The two commonest large bromeliads are *Aechmea nudicaulis* and *Gravisia aquilega* they form nearly a half of the total immortal community of bromeliads. *Gravisia aquilega* is by far the most important it is rare to find a plant that does not contain *A. bellator* larvae. It is equally rare to find *A. bellator* larvae in *Aechmea nudicaulis*. *A. bellator* does not occur in all the parts of Trinidad where cacao estates exist but is restricted to areas of high rainfall.

A. bellator occasionally enters dwellings to feed, but it leaves for forest cover immediately after-feeding. This behaviour precludes the possibility of control by spray killing adult mosquitoes. It has a well-marked evening flight but is active throughout the day in cacao plantations. The greater part of malaria transmission takes place either in the plantations where labourers are freely attacked especially on damp days or on the verandahs of houses in the evening.

As a malaria control measure the manual removal of bromeliads has been tried, but it is excessively costly. Moreover immortal trees are difficult and dangerous to climb. Large thorns cause bad scratches or open lacerations. scorpions spiders and snakes are harboured by the epiphytes. the limbs of the tree are extremely brittle and climbing is almost impossible when the tree is wet.

Spraying with copper sulphate solution can destroy bromeliads. a heavy spraying equipment developed by the U.S. Department of Agriculture for the control of the gypsy moth has been used with success.

A change in agricultural practice whereby shade trees are abandoned and the cacao trees protected by rows of trees planted perpendicular to the prevailing wind, is now being encouraged by the Government of Trinidad. For such windbreaks the mango tree would be suitable. Should this change materialize endemic bromeliad malaria should disappear from the centre of the Island.

Norman White

4 Blood protein tyrosine was elevated in many cases of acute epidemic hepatitis "

MOST H. & HAYMAN J M Jr Uncommon Clinical Manifestations of Vivax Malaria. *J Amer Med Ass.* 1946 Feb. 23 v 130 No. 8 480-85

Delayed primary attacks of malaria in the returned serviceman some time after the cessation of effective suppressive treatment may be bereft of the symptoms which characterize a typical attack and it may not be possible to find parasites in blood smears for some days. Persistence and patience in the examination of blood smears may result in finding *P. vivax* and useless treatment with penicillin or sulphonamides may thus be avoided.

Symptoms and signs suggestive of an abdominal disease may precede or accompany an acute attack of vivax malaria. blood smears should be examined carefully before recourse is had to surgery. The white blood cell count is rarely increased in malaria.

Convulsions may occur with attacks of vivax malaria as a reaction to hyperpyrexia or in patients with underlying brain disease. Pre-existing epilepsy head injury and *falciparum* malaria must be excluded. A stiff neck and fever may simulate meningitis.

Urticaria or severe angioneurotic oedema may precede or accompany acute attacks of vivax malaria.

Pulmonary signs and symptoms in attacks of vivax malaria may suggest a diagnosis of pneumonia in the winter months.

Surgical operations or trauma may reactivate vivax infections long after the last clinical manifestation of malaria.

Malaria does not exclude the possibility of other co-existing infections.

Norman White

Downs W G Results in an Infantry Regiment of Several Plans of Treatment for Vivax Malaria. *Amer J Trop Med* 1946 Jan. v 28 No 1 67-86
4 figs

This report deals with the experience of two battalions of an infantry regiment which were for periods of 189 and 164 days in 1942-43 on Guadalcanal a highly malarious island, and thence were transferred to Samoa which is malaria free for demalarialization. While in Guadalcanal, first quinine and then mepracrine suppressive therapy was administered but was not rigidly enforced except in the last two months of the regiment's service on that island. Forty-eight per cent. of the regiment suffered from malaria in Guadalcanal, and the monthly malaria incidence rates varied from 800 to 1,500 per 1 000 per annum. most of the diagnoses were clinical.

For demalarialization in Samoa where there were laboratory facilities different groups of men were subjected to different treatments. The results are recorded in detail. The conclusions are summarized as follows —

In troops almost universally infected with vivax malaria few or no individuals were cured of infection by suppressive atabrine therapy (0.4 gm. per week) administered for a period of six months during exposure on a malarious island.

Few or no cases of vivax malaria were cured by mass therapy with atabrine or with atabrine plus plasmodochin after leaving the malarious island.

" Initial attacks of malaria occurred as late as six months or more after discontinuing atabrine suppression or after mass therapy of any of the types employed.

" Atabrine mass therapy did not alter appreciably the number of first relapses occurring after first observed attacks.

There was a definite tendency to relapse between the fifth and seventh week after the first observed attack with a sharp peak in the sixth week. No difference in course of disease was noted between the group which had had malaria attacks previously on the malarious island and had first observed attacks during the course of this study and the group which had not had malaria attacks on the malarious island and had actual primary attacks during the course of study. (The total time span from date of first exposure to infection to termination of study was one year)

Plasmochin administered as a part of mass therapy apparently aided in lowering the peak rate of first observed attacks and spread the experience over a longer time period without appreciably altering the final outcome as far as first observed attacks and first relapses are concerned. There may have been a slight tendency to lower the ratio of total relapses to first observed attacks but this point is far from being clearly established and needs observation over a longer period of time

KNOW W E The Quinine-Oxidizing Enzyme and Liver Aldehyde Oxidase
J Biol Chem 1946 June v 163 No 3 699-711 4 figs [16 refs.]
Norman W Hile

A derivative of quinine was obtained by KELSEY *et al* [this *Bulletin* 1944 v 41 923] when minced rabbit liver was incubated with the alkaloid. It was shown by MEAD and KOEPLI [this *Bulletin* 1945 v 42 9] to be an oxidation product of the parent substance in which the hydrogen atom in the position adjacent to the nitrogen atom of the quinoline nucleus had been replaced by a hydroxyl group. The enzyme involved has now been prepared in approximately 5 per cent purity and its activity determined under standard conditions by the rate of reduction of methylene blue in the presence of cinchonidine as substrate. Rabbit liver was found to be the only satisfactory source of the enzyme which has been shown to oxidize quinoline isoquinoline and pyridine rings in the corresponding position to that found for quinine. The rate of oxidation was dependent on the reactivity of the hydrogen atom in that position. It is possible that the slower oxidation of certain substituted quinolines by enzyme action may help to explain their antimalarial activity. Plasmoquinone and substances with other heterocyclic or aromatic rings were not oxidized by this enzyme which has properties similar to those of liver aldehyde oxidase. It is soluble in water resistant to a temperature of 60°C for five minutes and is precipitated at 25-40 per cent saturation with ammonium sulphate. In properties it resembles a similar preparation from pig liver. Whereas that from rabbit liver could oxidize quinolines as well as aldehydes the other preparation reacted with aldehydes only. The enzymes from the respective sources are both flavo-proteins. No separation of the substances involved in the oxidation of quinolines or aldehydes could be achieved, and in the presence of both types of substrate the rate of reaction was slower than with either type alone. The mutual interference by the two substrates suggests that both reactions share a common element in the pathway of oxidation which available evidence suggests to be the flavin group

J D Fulton
MOST H & HAYMAN J M Jr Relative Efficiency of Quinacrine (Atabrine) and Quinine in Treatment of Acute Attacks of Vivax Malaria. *Amer J Med Sci* 1946 Mar v 211 No 3 320-24 2 charts

Three hundred and ninety-seven patients with acute attacks of *P vivax* malaria with fever and parasitaemia were treated with mepacrine (quinacrine). All treatment was begun on the day following the onset of the attack. On the first day of treatment 1 gm of mepacrine was given by mouth, in three divided

doses. On the succeeding six days 0.1 gm. was given three times a day after meals. The total dose given over the seven-day period was thus 2.8 gm. Parasite counts were done twice daily and continued till negative for three consecutive days. Plasma-mepacrine levels were determined on the 2nd and 8th days. The patients left the ward on the 8th day and 200 of them were observed for 120 days or till relapse. During this time smears were examined twice weekly. A rise of mouth temperature over 100°F associated with parasitaemia was considered a relapse and the patient was re-admitted to hospital.

One hundred similar patients were treated with quinine the treatment starting the day after the onset of the attack. On the first day 1 gm. was given thrice at intervals of 8 hours. On each of the following 13 days 2 gm. were given in three divided doses. Thus 29 gm. of quinine sulphate were given by mouth during the 14 days. Minimum and maximum plasma-quinine determinations were made on the 2nd, 7th and 14th days of treatment. The other observations were the same as described for the mepacrine group.

Mepacrine cleared the peripheral blood of parasites more rapidly than did quinine. At 48 hours from the commencement of treatment, 77 per cent. of the mepacrine patients were free from parasites as compared with 44 per cent. of the quinine patients.

Of the patients treated with mepacrine 7 per cent. had fever of 100.2 or higher on the 2nd or 3rd day of treatment, as compared with 10 per cent. of those treated with quinine. In the treatment of delayed primary attacks of river malaria, 32 per cent. of patients treated with quinine had fever on the 2nd or 3rd days as compared with 16 per cent. of similar patients treated with mepacrine.

All concerned with these observations were agreed that mepacrine is more effective than quinine in the prompt control of symptoms of an acute attack of malaria.

With regard to toxicity the only points in favour of either drug are the absence of tinnitus with mepacrine. Rare cases of idiosyncrasy or sensitization to either drug may occur. Patients with eczematoid or exfoliative dermatitis and acute malaria should not be given mepacrine if they have had the drug before.

Eighty per cent. of Pacific infections relapsed within the 120 days of observation regardless of the drug used in treatment. The mean interval to relapse after mepacrine was 53 days, and after quinine 22 days.

The observations show that mepacrine is superior to quinine in the treatment of acute attacks of river malaria.

TOOMEY A. G. Aspects of the Treatment of Subtertian Malaria. *J. Roy. Nav. Med. Serv.* 1946 Jan v 32, No 1 32-8 1 fig

This paper is based on the treatment of 883 adult European patients suffering from *P. falciparum* malaria in Freetown, Sierra Leone during 1943-44. Various forms of treatment are compared. Mepacrine was preferred to quinine, relapses were fewer after its use. The average amount of mepacrine given in a twelve-day course was 5.4 gm. 1.2 gm. the first day, 0.9 gm. the second day, 0.6 gm. the third day, and 0.3 gm. daily thereafter till the end of the course. In 157 cases the dose of mepacrine was doubled on each of the last four days of the course during which the patient was given graduated walking and running exercise. When necessary mepacrine was given by both intramuscular and intravenous routes without any ill effect. It was preferred to quinine similarly administered. After the introduction of mepacrine as a suppressive, pamaquin was badly tolerated and its use in treatment was discontinued. [Pamaquin is

said to have been given in doses of 0.1 gm. thrice daily for four days probably a misprint for 0.01 gm.]

GORDON H. H. MARBLE A. ÉNGSTROM W. W. BRUNSTING H. A. & LIPPINCOTT S. W. Relapses following Delayed Treatment of naturally Induced *Vivax* Malaria of Pacific Origin. *Science* 1946 Mar 29 391-2. [10 refs.]

Sixty nine white soldiers who required malaria therapy for neurosyphilis were infected with U.S. anophelines which had previously been fed on soldiers infected with *P. vivax* malaria acquired in the Pacific area. Antimalarial treatment (2.8 gm mepacrine in 6 days) was delayed in the patients suffering from neurosyphilis until they had had from 8 to 15 paroxysms with an average of 40 hours of fever over 104° F. This level was reached on the average in 20 days during which blood smears revealed *P. vivax*. The patients were then observed till a relapse occurred or for at least 60 days without a relapse. Thick blood smears were examined twice weekly.

Forty five patients (65 per cent.) had a relapse. There was no significant difference between the mean hours of fever above 104° or between the mean days of parasitaemia in those patients who relapsed and those who did not. The relapse rate was not markedly different in another group of 124 patients suffering from Pacific *P. vivax* malaria whose attacks were promptly treated with mepacrine in the Harmon General Hospital.

Seventy-six per cent of the relapses following delayed treatment occurred within 59 days and 93 per cent. within 89 days of the termination of treatment.

Relapses occurred in men infected with 7 of the 10 strains of *P. vivax* used. Only 7 men had been infected with the 3 strains that caused no relapse. The importance of the strain in determining relapse rates is illustrated by the fact that only 2 of 16 soldiers infected with *P. vivax* of the Mediterranean origin relapsed and these after intervals of 111 and 189 days from the termination of mepacrine treatment. No relapse followed the primary manifestations of infection induced in 28 men by the intravenous inoculation of trophozoites of Pacific strains which had caused very high relapse rates when infection had been conveyed by mosquito bite. No evidence was forthcoming that early treatment of malaria attacks delays the development of immunity.

GINSBERG J. E. & SHALLENBERGER P. L. Wood's Light Fluorescence Phenomenon in Quinaquine Medication. *J Amer Med Ass* 1946 July 6 v 131 No 10 808-9

Ginsberg accidentally observed that his finger nails emitted a bright greenish-yellow fluorescence when he was examining a child for tinea capitis under Wood's light. He had recently returned from the tropics and presumably his skin and its appendages were still stained with mepacrine. Shallenberger had made a similar observation whilst making an earlier study concerning deposits of the drug in the hard palate and finger nails (*Arch Dermat & Syph* 1946 v 53 349).

These authors collaborated in a study of 511 patients. 158 of whom had taken mepacrine. In 79 of the latter the greenish yellow fluorescence did not occur but 55 had not taken the drug for 13 months. On investigation it was found that the characteristic fluorescence occurred in all subjects who were on mepacrine therapy or "sound prophylaxis". The fluorescence could be noted for three to six months after the drug was discontinued, but as the nails grew the proximal areas showed the normal fluorescence of healthy nails (violet blue in colour) whilst the distal parts showed the greenish yellow hue referred to above.

The toe-nails cleared more slowly than the finger nails frequently the nails of the big toes remained fluorescent longer than the others sometimes for as long as a year after mepacrine therapy or prophylaxis ceased.

Unusual fluorescence phenomena did not occur in patients receiving numerous other drugs including penicillin and sulphonamides.

Mepacrine tablets and aqueous solutions have a brilliant yellow fluorescence under Wood's light.

The authors suggest that there is a longer delay in the complete excretion of mepacrine from the body than has previously been reported, and consider that their observation confirms that made by LUTTERLOH and SHALEMBERGER (references quoted above) concerning mepacrine deposits which may be seen as bluish pigmentation under the nails when examined in daylight.

[Wood's light—so called—is an ultra violet ray filtered through glass containing nickel oxide (Wood's glass) which restricts the passage of all but relatively long wave ultra violet light of about 3 650 Å the light is commonly used for the rapid diagnosis of tinea capitis since hairs infected with *Microspora* emit a characteristic green fluorescence

KIERLAND R. R. SHEARD C. MASON H. L. & LOBITZ W. C. Fluorescence of Nails from Quinaerine Hydrochloride. *J Amer Med Ass* 1948 July 6 v 131 No 10 809-10 1 fig

Kierland who had just returned from the south-west Pacific area where he had been taking mepacrine daily for almost two years, noted a brilliant yellow-green fluorescence of his finger nails under Wood's light. He and his colleagues have noted this phenomenon in nine other persons all of whom had taken mepacrine for from 5 to 21 months. They noted that the fluorescence begins to fade three months after the drug is discontinued, and that it usually disappears in six or seven months. In their opinion the blue-black pigmented areas of the nailbeds and hard palate which have been noted in persons taking mepacrine for long periods do not fluoresce neither does the skin or hair of these subjects further their teeth do not show an abnormal fluorescence.

The exciting wavelength of the Wood's light used in this study was 3 500-4 000 Å the wavelength of the light emitted by the fluorescing nails was 5 400-6 000 Å. The fluorescent wavelength of solutions extracted from the skin nails and hair of a person receiving mepacrine was 5,300-5,800 Å. Quantitative photofluorometric determinations were made of the skin and its appendages in three persons. The results are tabulated thus —

Mepacrine in Micrograms per Gram of Tissue

Nails	Hair	Skin
1 2.6	1 27.2	1 10.4 wet weight
2 5.2	2 47.6	23.1 dry weight
3 0.63		

This person had discontinued taking mepacrine three and a half months before the clippings of nail were obtained.

The authors suggest that it would be interesting and valuable to determine the amounts of mepacrine in the affected and non-affected areas of skin of persons with the atypical lichen planus syndrome.

LIPPINCOTT S W ELLERBROOK L D HESSELBROCK W B CARRICO C C & MARBLE A The Relationship of Spinal Fluid to Plasma Concentrations of Quinacrine and Quinine *J National Malaria Soc* Tallahassee Fla 1946 Mar v 5 No 1 85-91

The concentration of quinacrine (atebrin mepacrine) and quinine has been simultaneously determined in the plasma and spinal fluid of two groups of neurosyphilitic patients as a guide to the mode of action and effectiveness of these drugs in cerebral malaria. In one experiment 51 patients divided into 7 groups were given quinacrine in the form of atebrin dihydrochloride in doses ranging from 0.5 to 3.0 gm. over a period of 1-3 days so that the plasma concentrations equalled or were greater than those obtained during therapy. These concentrations were maintained for different periods the range encountered being from 18 to 135 micrograms per litre for plasma and from 0 to 6 micrograms per litre in the case of spinal fluid, the values for a large percentage of the latter being within the range of error of the method. Specimens of plasma and spinal fluid were obtained from 2 to 61 hours after the last dose of drug the latter being withdrawn immediately prior to the venous blood specimen. The method of BRODIE and UDENFRIEND [this *Bulletin* 1944 v 41 453] was used for the estimation of atebrin after trial and with slight modifications for quinine. In spinal fluid, the concentration of quinacrine varied from 0 to 15 per cent of that in plasma and the ratio was not appreciably affected, in the different groups by variation in conditions of dosage and withdrawal. In similar experiments quinine sulphate dihydrate was given to 44 subjects in doses ranging from 0.5 to 3.0 gm. during twenty four hours. Specimens were obtained from 2.0 to 3.5 hours after the last dose. The plasma levels at their peak values varied from approximately 1 000 to 7 000 micrograms per litre in six different groups on different dosage schedules. The corresponding variations in spinal fluid level were from 19 to 260 micrograms per litre. The maximal ratio of the latter to that in plasma in one case reached 9 per cent but was generally much lower. It appears that the ratio increased in proportion as the plasma concentration was increased, and as the time of maintenance of the latter lengthened. The authors believe that the mechanism of exchange of quinacrine between plasma and spinal fluid is one of diffusion. Both drugs are probably bound to protein in plasma and hence the smallness of the spinal-fluid/plasma ratio. It is doubtful if the concentrations of quinacrine and quinine in the spinal fluid obtained with the non toxic doses used could be of therapeutic value in cerebral malaria if these drugs were in combination with protein. *J D Fulton*

WILLIAMSON ANNE HEGSTED D M MCKIBBIN J M & STARE F J The Effect of Variations in the Level of Dietary Calcium upon the Growth of Young Rats receiving Atabrine *J Nutrition* 1946 June 10 v 31 No 6 647-55

When recently weaned male rats were given a standard diet to 100 gm of which 40 to 60 mgm. of mepacrine was added the rate of growth was significantly lowered as compared with that of controls given no mepacrine. This inhibition of growth was more marked when the diet contained 1.35 per cent. of calcium than when it contained either 0.55 or 0.15 per cent. The concentration of mepacrine in the liver was much greater in animals given the high calcium diet than in those given the low calcium diet although the intake of mepacrine was approximately the same in the two groups. The concentration of mepacrine in the liver was the same after 30 days and after 63 days of treatment.

The reaction of the contents of the distal small intestine and caecum was more alkaline in the animals taking the high calcium diet. The addition of various

salts to the diet failed to show any effect of alteration of intestinal pH upon the toxicity of mepacrine. Some animals on the high calcium diet exhibited renal calculi which may have impaired the excretion of mepacrine. It is therefore not clear whether the increased toxicity of mepacrine when combined with a high calcium diet is due to increased absorption, decreased excretion, or to a specific effect of calcium on mepacrine metabolism. *H E Harding*

IMPERIAL CHEMICAL (PHARMACEUTICALS) LIMITED. BIOLOGICAL DEPARTMENT
Paludrine—a Summary of Information to February 1946 [DAVEY D G]
1946 Mar 1 13 mimeographed pp. [19 refs.] [Report No B T 1166.]

This is a most useful summary of information about Paludrine. Work on this drug is still being continued because there are points on which insufficient information exists but this account by bringing together all the available results of investigation, presents a picture which will be of very great value to those who work on the chemotherapy of malaria and no less to those who must plan ahead for treatment policies.

To attempt an abstract of this already condensed summary would scarcely be possible—it is enough to indicate briefly some of the conclusions which existing work permits. The author assumes by analogy that exo-erythrocytic forms of the human malaria parasites exist, though he admits that they have not yet been found.

Two salts of Paludrine have been used the monohydrochloride and the monoacetate each is sparingly soluble in water. The fatal dose for acute poisoning in animals is from 25 to 80 mgm. per kgm. for chronic poisoning from 20 to 60. Paludrine is rapidly absorbed and excreted, chiefly in the urine though the blood concentration is much diminished 12 hours after administration, a build up may be effected if doses are taken twice each day.

In man one to three daily doses of 100 mgm. or less [these are total doses, not doses per kgm.] may completely and permanently prevent *P. falciparum* from gaining access to the blood stream even if taken on the day after exposure to infected mosquitoes. There is evidence of an inhibitory action on the presumed exo-erythrocytic forms of *P. vivax* but the fact that relapses do occur after cessation of this treatment shows that the action is not lethal.

The suppressive effect of Paludrine is almost perfect—a daily dose of 25 mgm. is enough completely to suppress subtertian, and of 100 mgm. to suppress benign tertian, malaria. Moreover since a single dose of 100 mgm. is enough to control a clinical attack so that relapse does not occur for several weeks the same dose given once each week, is likely to be an efficient suppressive dose.

In man, slight toxic symptoms may be produced with 500 mgm. twice daily for 28 days—single doses of more than 750 mgm. should not be given. In treatment it is wise to distinguish between clinical cure and radical cure. In subtertian malaria the former can be achieved by a single dose of 100 mgm. or by repeated doses of 50 mgm. the latter by 100 mgm. t.i.d. for 10 days. In benign tertian malaria clinical cure can be achieved by similar doses but radical cure cannot be guaranteed—relapses do occur though with bigger doses up to 500 mgm. twice daily for 14 days patients are apparently slow to relapse. After treatment patients may be released with a supply of Paludrine to be taken as a weekly dose of 100 mgm. for several months. In quartan malaria Paludrine apparently has good effect but there have been too few cases to make general claims. Intravenous injections have been used, and in subtertian malaria a dose of only 5 mgm. given by this route has marked effect.

Paludrine does not destroy gametocytes but renders them non-effective for mosquitoes for several days—this seems to be due to the action of the drug while in the stomach of the mosquito.

The author quotes much already published work, most of which has already been abstracted in this *Bulletin*

MOST H LONDON I M KANE C A LAVIETES P H SCHROEDER, E. F & HAYMAN J M Jr Chloroquine for Treatment of Acute Attacks of Vivax Malaria. *J Amer Med Ass* 1946 July 20 v 131 No 12 963-7 5 charts

A report on the activity of the antimalarial drug chloroquine (SN 7618) 7-chloro-4-(4-diethylamino-1 methylbutylamino) quinoline which was recently synthesized in America has been reviewed [this *Bulletin* 1946 v 43 708] In the present study its value in the treatment of acute attacks of malaria due to infection with *P. vivax* acquired in the Pacific and Mediterranean theatres of war has been investigated in primary and relapse cases. More than 500 patients were treated whom it was possible to follow up until relapse occurred or for a period of 120 days after the end of treatment. The cases were grouped according to origin and stage of infection. Several dosage schedules were employed in which 0.8-2.0 gm of the drug was administered and 50-75 cases were treated in each group. The schedules in which 1.0 gm was given on one day 1.5 gm. in 4 days or 2.0 gm. in 7 days proved satisfactory. Comparison was also made of the results obtained in patients treated with 2.8 gm. quinacrine (atebrin) during a period of 7 days or with 29.0 gm. quinine during 14 days. It was found that chloroquine freed the peripheral blood from parasites abolished fever and controlled other symptoms more rapidly than the other two drugs. No major toxic manifestations were caused by chloroquine but about 20 per cent. of the patients had general or localized pruritus of a slight or transient character. In 2 per cent. pruritus was accompanied by skin eruptions. Relapse rates 120 days after treatment were slightly lower than with quinine or atebirin, but these relapses with the new drug occurred much later in the observation period. Malaria acquired in the Pacific was more prone to cause relapses than that acquired in the Mediterranean area and no radical cures were obtained with any of the drugs. Plasma levels of chloroquine are recorded for 176 patients treated as above and it was found that a minimum concentration of approximately 10 micrograms per litre was necessary to control an acute attack. [After therapeutic doses of Paludrine 10-100 micrograms of the drug are present per litre of plasma.] The authors summarize the reasons for their conclusions that chloroquine is a safe and highly effective drug which is superior to quinine and quinacrine under the above conditions of test. A course of treatment for acute attacks of malaria due to *P. vivax* is outlined.

MADINAVEITIA J The Antagonism of some Antimalarial Drugs by Riboflavin. *Biochem J* 1946 v 40 No 3 373-5 1 fig

In an investigation relating to the mode of action of antimalarial drugs the antagonism by these and other compounds of riboflavin an essential metabolite

for *Lactobacillus casei* has been studied. For this metabolite which the organism cannot synthesize and which plays a part in enzyme systems an extraneous supply is necessary. The present indirect approach to the problem was made because of the lack of knowledge of the essential requirements of malaria parasites. The explanation of the action of a drug in some cases appears to depend on the fact that it bears a similarity in molecular shape to the metabolite. Such similarity in structure between riboflavin and certain antimalarials has been indicated by CURD *et al* this Bulletin 1946 v. 43 394. A suitable medium for the lactobacillus is described, in which growth was measured turbidimetrically. To observe the effect of riboflavin on the inhibition of growth by drugs the former was made up in various concentrations in the medium which was then sterilized and inoculated with the test organism in bulk. To series of tubes containing the drugs for assay in various dilutions was added the medium with the organism and the different concentrations of riboflavin. After incubation the presence or absence of growth was determined. Of the various substances tested, it was found that only those having antimalarial properties were antagonized by riboflavin the effect being most marked at relatively high concentrations of the latter.

- i. TOKKIN Isabel M. & WORK T. S. A New Antimalarial Drug [Correspondence] *Nature* 1945 Nov 24 630
- ii. MUKERJI B. Antimalarial Drugs of the Indigenous Materia Medica of China and India. [Correspondence] *Ibid* 1946 Aug 3 170.

i. The authors have made animal experiments with samples of two Chinese plants reputed to possess antimalarial properties. These were *Fraxinus malacophylla* and a root known as *chang shan* which is reputed to be *Dicksonia febrifuga*.

The first plant was found to be without action on *Plasmodium gallinaceum* in chicks. Extracts of the second plant showed considerable activity against a trophozoite-induced infection of *P. gallinaceum* in chicks. No alkaloid could be found in either plant.

ii. Mukerji also tested *F. malacophylla* on simian and human malaria. His observations confirmed those of TOKKIN and WORK (see above) in the case of chicks [although in fact he claims that these authors' observations differed from his since they recorded considerable activity against *P. gallinaceum* in chicks. In fact this statement as will be seen above referred, not to the use of *F. malacophylla* but to *D. febrifuga* (*chang shan*)].

In benign and malignant human malaria Mukerji could find no proved antimalarial effect on the part of *F. malacophylla* using it in three forms but in two of four cases a temporary febrifugal effect with a brief disappearance of the malarial parasites was recorded both cases relapsed.

The same phenomenon was observed with two indigenous Indian drugs *Cassia alba* and *Cassia bonducella*. The author also examined *F. malacophylla* with success in the treatment of human malaria in India and China, and concluded that indigenous vegetable drugs with a slight febrifugal effect are of value in the treatment of malaria.

- i. HEIDELBERGER M COATES W A & MAYER M M Studies in Human Malaria. II Attempts to Influence Relapsing Vivax Malaria by Treatment of Patients with Vaccine (*Pl vivax*) *J Immunology* 1946 May v 53 No 1 101-7
- ii. — PROUT C HINDLE J A & ROSE A S Studies in Human Malaria. III. An Attempt at Vaccination of Paretics against Blood-borne Infection with *Pl vivax* *Ibid* 109-12.
- iii. — MAYER M ALVING A S CRAIGE B Jr JONES R. Jr PULLMAN T N & WHORTON M Studies in Human Malaria. IV An Attempt at Vaccination of Volunteers against Mosquito-borne Infection with *Pl vivax* *Ibid* 113-18 1 fig

1. The authors have attempted to influence the relapse rate in chronic cases of benign tertian malaria by the use of a vaccine prepared from infected blood, as described in Part I of this series [this *Bulletin* 1946 v 43 816]. Three groups of approximately 60 men who had contracted *vivax* malaria in the S W Pacific were used. One group which served as control received only routine treatment with drugs. A second group received drug treatment for the primary attack only and was then vaccinated as described below. The third group was treated like the second, the vaccine in this case consisting of red cell stromata obtained from normal blood by treatment similar to that used in preparing the vaccine from parasitized blood. Some members of the groups had at various times previous to the start of experiment received atebain in suppressive doses. Each group was sub-divided into two according to blood groups as previous experiments of other authors had shown that high α -agglutinin titres may be immunologically significant in malaria. In the present experiments however no increase of α -agglutinin was noted in subjects of blood group O after injection of normal or infected blood from group A subjects. The average period of observation of these cases was 7-8 months. The amount of vaccine for each person corresponded to 2-6 billion parasites or an equivalent amount of normal red cell substance. It was given in divided doses by the intracutaneous (10 per cent) subcutaneous (40 per cent.) and intravenous routes (50 per cent.) over a period of 4-5 days. In a few cases 2 or 3 courses of vaccine treatment were given only Rh-negative vaccines and stromata being used on Rh-negative individuals. There were only minor untoward reactions as the result of treatment. It was found that immunization with vaccine or stromata had no effect on the relapse rate.

ii. Previous attempts at active immunization in human malaria with inconclusive results were reported by KONSTANOFF [this *Bulletin* 1930 v 27 663] and by SCHILLING [*ibid* 1940 v 37 368]. The present authors have made the first controlled vaccination experiments against a primary attack of benign tertian malaria. Vaccines were prepared as already described with the McCoy strain of *P vivax*. Three neurosyphilitic white males without previous history of malaria were used in the tests. The vaccine containing a total of approximately 4 billion formalized parasites was administered by the same three routes as in Part II above in two courses lasting 3-5 days with a week interval between each course. The patients were injected with $\frac{1}{2}$ -5 million parasites of the same strain 19-22 days after the last dose of vaccine. The subsequent results of inoculation were the same in those vaccinated as in controls. Two of the vaccinated were given quinine when the malarial attack developed and further tested for immunity by reinoculation with infected blood 13-16 days later. It was concluded that no protection had been afforded by vaccination.

iii. In this series of experiments protection was attempted against the bites of mosquitoes infected with *P vivax* Chesson strain by vaccines prepared

FOURCHE & RICKLIN [this *Bulletin* 1929 v 26 183] and FOURCHE & HAVZAUX [this *Bulletin* 1932 v 29 305]. Further details are given in the present report. The duration of protection was judged to be about 6 months.

Results Sector by Sector—Separate detailed accounts, covering 10 pages of text, are given of the work done in each of nine geographical sectors. These do not lend themselves to summary. References are made to population-displacements found to be necessary in several zones of the Tshikapa-Lutshiko sectors.

In an interesting concluding section the author outlines the way in which mass movements of populations due to dynastic quarrels, inter-tribal warfare, railway and industrial developments, etc., have conduced to the spread of sleeping sickness. Apparently the infection has converged upon Tshikapa, through these population-movements both from the west and from the East.

From the west came the Bampende from the River Kwango installing themselves in the lands of the long-settled lesser tribes and other important invaders were the Lunda. Not long before the arrival of the Europeans a further wave swept over from the west—the warlike Batshok, "*les prussiens de l'Empire*"—kinsmen and rivals of the Lunda, burst into the Kasai, enslaving the populace except for the Bampende who recoiled before the invasion, and it is this movement of the Batshok, in particular, to which the author ascribes the spread of infection from the Kwango into the Kasai which was recognized in 1923.

Well over to the east on the banks of the Boshumai and the Lomami, and beyond, the first Europeans put an end to the internecine warfare of the Baluba but ineradicable hatreds and rivalries remained. In order to ensure the authority of the Chiefs recognized by the State it became necessary to separate the dissident groups. They were moved westward, first to Luluabourg, then to Luebo Tshikapa, etc. This was the first wave of infected Baluba tribesmen towards the Kasai. The subsequent building of a railway in the Dibaya and Luluabourg territories gave rise to further population-shifts with still further spread of sleeping sickness into these particular areas from which infection was brought into Tshikapa by the recruitment of labourers.

[There are no detailed references to tsetse flies or to tsetse fly control, in this report.]

E. M. LOUIS

McLEITCH, J. L. The Control of Sleeping Sickness in Northern Nigeria. *Farm and Forest*. Ibadan Nigeria. 1945 Apr-June, v 6 No 2 69-79

The Anchau Settlement in the Zaria and Kano Provinces of Northern Nigeria has previously been mentioned in this *Bulletin* but the account given by the present author is the first seen by the reviewer in which the administrative details have been fully described. The settlement was conceived as part of the scheme for the control of trypanosomiasis, in view of the fact that control by mass treatment, although highly successful, could not be regarded as a final answer to the problem, in that it seemed impossible by that method alone completely to eradicate the human disease; moreover mass treatment was not applied to cattle. The area of the Settlement was chosen because it seemed probable that complete eradication of tsetse could be achieved and maintained by an effort not beyond the capacity of the population—the corridor which will eventually be rendered free from fly is about 70 miles in length and comprises 700 square miles. In this corridor the people from surrounding (and infested) districts are, or will be concentrated—they will be protected from fly but the fact of concentration and removal to strange surroundings must inevitably introduce new problems, medical, veterinary, agricultural and social. All these

problems must be solved many were anticipated and provided for but others could not be foreseen

The work was started in 1937 with a grant from the Colonial Development Fund of £95 000 to be spread over five years and during the same period the Nigerian Government proposed to increase expenditure on the treatment service by £55 000. The tsetse control staff included 14 Europeans—two entomologists one District Officer one well sinking foreman and ten Control Officers. The scheme was controlled by the Sleeping Sickness Service but a committee from all the departments concerned was created to advise on policy. [Dr McLetchie wishes it to be made clear that Dr H M O LESTER was primarily responsible for the conception of the Anchau scheme and that in the early years of development Dr T A M NASH was in local charge at Anchau.]

In 1938 and 1939 the preparatory work was initiated basic investigations were made and staff was trained. In 1940 and 1941 movements of the population were made into the Settlement and clearings were extended. Thereafter because of the war the work was placed on a maintenance basis until later in 1942 there was a gradual resumption of tsetse surveys research clearing well-sinking and general development.

The amount of work done is indicated in the body of this paper but the great difficulties always met in any attempt to change the habits and customs of an intensely conservative people are hinted at rather than stressed. The peasants are Moslems some lived in reasonably prosperous villages but many were on a bare subsistence level and were not good farmers. Guinea worm infection was rife and contact with tsetse very close. It was necessary to assess the fertility of the land to which the people were to be moved a difficult task since no accurate scientific method of assessment for this area was known. Nevertheless a pointer was recognized by an Agricultural Officer which was the presence of certain trees and the density of growth of grass. Certain plots were cleared and four staple crops planted in each growth and yield were correlated with soil and vegetation types and the association of the trees mentioned above with fertile soil was established. New village sites could now be chosen after extensive survey and mapping had been done. Land was divided among the householders according to native practice by the headmen of the hamlets. Compounds were dispersed singly or in groups the layout now advised is a group of houses round a central well-space 100 feet square. The compounds themselves are 100 feet square and are separated from each other by a space of 100–125 feet. Huts are 12 feet in diameter and 12 feet apart.

In the first period the technique of stream clearance was standardized and over 300 miles of stream were cleared. Within the Settlement area streams are partially cleared mahogany and other valuable high branching trees being left at intervals. To prevent re-infestation of these streams by tsetse from the uncleared rivers outside the corridor a barrier clearance straddles the corridor boundary. The barrier is a mile in length 50 to 100 yards broad and is cleared ruthlessly.

The sinking of wells and the protection of well-heads was carried out on a large scale. Fruit trees and other sources of foodstuffs were introduced and the disposal of rubbish and animal manure was given attention.

In the dry seasons of 1940 and 1941 the major population movements were made water supplies were improved and anti tsetse clearances were extended. By the second year 16 new villages and seven extensions to existing villages were completed. Pit latrines were introduced to all compounds and the authorities insisted on their use and care. The value of a combination of partial and barrier clearance was now proved and clearing was therefore extended. The organization of annual re-slashing of already cleared areas was even more

laborious than initial clearing this is done on a communal basis and requires about four days work from each adult male. Villagers re-slash well the more sophisticated people of large towns badly. Moreover people from the shums of old Anchan did not cooperate well, and were poor farmers. Experiments with new crops were made and continued and an estimate of fuel requirements (15 cwt of wood per person each year) was made and fuel areas calculated accordingly were marked out.

Cotton and ground-nut markets were opened, the preparation of hides for export was taught, soya cultivation was introduced and sugar production encouraged. Cattle were inoculated against rinderpest but trypanosomiasis interfered seriously with the cattle programme. This disease was transmitted, not by tsetse but by other blood-sucking flies. Fodder for livestock became scarce but arrangements were made to cultivate it.

By the end of 1942 the people had accepted their new life cheerfully but continued supervision was very necessary. After that the programme of expansion in abeyance for 18 months was resumed and improvements were made within the corridor. A demonstration farm was opened and schools were started in all districts and in many villages.

The only human diseases mentioned in this paper are cerebrospinal meningitis, smallpox, guinea-worm and trypanosomiasis. Outbreaks of the first two occurred but were controlled, and the value of treatment for meningitis and of vaccination for smallpox, are apparent to the people. Guinea-worm which creates havoc in parts of Nigeria will presumably be controlled as good wells come into use and human trypanosomiasis will not be a problem so long as anti-tsetse measures are maintained. Mosquito breeding is mentioned but not discussed.

[The Anchan settlement is the biggest concentration of population yet made in Africa, and offers, perhaps the best opportunity for introducing to the African a mode of life far more beneficial than anything he has yet known but it seems evident that supervision will be needed for many years to expect of the African a rapid abandonment of conservatism would be unwise. It is necessary to take a long view.]

Charles W. Wilcocks

CLARK J. D. Pattern for Progress in Rural Africa. Oversea Education 1948
Apr. 17 No. 3 295-301

This account of the Anchan Corridor gives much the same information as is given by McLEITCH (above) but adds emphasis on some of the points. The author notes with approval the fact that when the scheme was first mooted as a measure of control of trypanosomiasis the medical authorities were not content that it should merely offer protection against that disease, but decided, in collaboration with other departments that the whole area should be developed in the economic and social sense and that an advanced degree of rural hygiene should be encouraged. The population aimed at was not less than 70 to the square mile at which communal clearing is possible.

The new villages are now most attractive and people from outside the area apply to be allowed to settle in them. In these rural schemes there has been a mixture of compulsion and persuasion. In the opinion of the Control Officers the people appreciate the new way of life, but need supervision to ensure that the present high standards are maintained. One of the most important activities is the education of the people themselves, in the small schools which have been instituted. This is not education reserved for the few who show promise but simple instruction for the many who may because of it be influenced towards the desire for better conditions than they have demanded in the past.

So far the scheme has cost £15 000 per annum which represents 5s per head of the population affected. The maintenance cost will now be reduced to one-fifth of these figures. Such expenditure is obviously worth while in terms of the health and welfare of the people. Anchau is not merely a method which ought to be widely used in the control of endemic disease. It is an example to all departments of government.

The author was cheered by the sight of a job well done. It was refreshing to visit a scheme which has been carried out without counting the pence and which has therefore been a success.

AUGUSTINE D. L. Some Factors in the Defense Mechanism against Reinfection with *Trypanosoma lewisi*. Reprinted from *Proc Amer Acad of Arts & Sciences* 1943 May v 75 No 3 85-93 5 figs on 1 pl [10 refs]

The author has studied the mechanism of immunity of rats to reinfection with *Trypanosoma lewisi* by examining the peritoneal fluid, the lymph nodes which drain this fluid, and the blood after intraperitoneal inoculation of large numbers (200-900 million) of trypanosomes. It was demonstrated that the trypanosomes passed as readily through the lymph nodes to the blood in rats which had recovered from a previous infection as in rats which had had no previous infection. In recovered rats however the trypanosomes arriving in the blood were rapidly removed within a few minutes to four days. The length of time of survival depends upon the titre of the antibody and the stage of development of the trypanosome in the blood. Dividing trypanosomes are almost immediately sensitized by the antibody being either killed or immobilized and are finally phagocytized by blood macrophages. Adult trypanosomes are more resistant and survive till the titre of the antibody reaches a point at which they are agglutinated into masses of living trypanosomes which are filtered from the blood in the internal organs where they are destroyed. The fact that the trypanosomes in the blood may commence dividing shows that any ablastin remaining from the first infection, which functions by stopping reproduction is inactive and plays no part in the immunity to reinfection. This immunity is dependent upon a humoral trypanocidal antibody to which developing parasites are particularly susceptible and adult parasites relatively resistant.

Several soil fungi have been found to produce filtrates active against *Trypanosoma equiperdum*. From a *Phycomyces* sp. a lipid-like substance was

isolated which immobilized the trypanosome *in vitro* but exerted no protective action against the experimental infection in mice.

No inhibitive agent has heretofore been obtained from this group of fungi. The selective action of the phycomyces factor against the trypanosome but not against bacteria, is of particular interest.

DAVIS D J & SULLIVAN Thelma de S. Complement Fixation Tests for American Trypanosomiasis in Texas. *Pub Health Rep Wash.* 1946 July 19 v 61 No 29 1083-4

Complement fixation tests, in which *T. cruzi* antigen was used, were carried out on (1) 1,009 samples of serum, of which 568 were from persons who lived largely in shelters harbouring triatomid bugs (2) 1,002 Kline-negative samples chiefly from counties where *T. cruzi* had been demonstrated in insects and (3) 339 samples which had been negative to ordinary routine clinical diagnostic tests.

The only serum found to fix complement in a significant dilution was from an 8-year-old boy living in a neighbourhood where many specimens of *Triatoma gerstaeckeri* had been found to be infected with *T. cruzi*. No further evidence that he was infected was obtained by clinical examination or animal inoculation.

NÁJERA ANGULO L. Hallazgo de *Phlebotomus* en Galicia y consideraciones sobre la epidemiología de las leishmaniasis. [Finding of *Phlebotomus* in Galicia. Epidemiology of Leishmaniasis.] Reprinted from *Boletín de la Real Soc Española Hist. Nat. Madrid*. 1945 v 43 25-30 2 figs

The author discusses the distribution of sandflies in the various provinces of Spain in relation to the existence of leishmaniasis visceral or cutaneous. He shows that recent observations have disclosed sandflies, chiefly *Phlebotomus perniciosus* in certain provinces even to a height of 1,500 metres, where their presence was previously unrecorded. These observations reduce the number of provinces in which both sandflies and leishmaniasis have not been demonstrated and it seems probable that careful observations by both clinicians and entomologists will fill the lacunae. The author shows in a map how close is the correspondence between the distribution of sandflies and leishmaniasis.

NÁJERA ANGULO L. La existencia de lesiones cutáneas en la leishmaniosis visceral mediterránea y su significación epidemiológica. [Epidemiological Significance of Cutaneous Lesions in Kala Azar] Reprinted from Rev Clin Española 1945 Jul 15 v 18 No 1 28-37 4 figs. (12 refs) French summary.

Having encountered a case of kala azar in Spain in a boy who was suffering at the same time from ulcers on the lower lip and leg (in which however leishmania could not be demonstrated) the author discusses the world distribution of kala azar with particular reference to the disease as seen in Southern Asia and the Mediterranean region. He believes that from the point of view of the tendency to cutaneous ulceration and other lesions of other specific characteristics and of the co-existence of canine kala azar this area is divisible into three zones separated by a line running from a point just west of the Crimea and crossing the Mediterranean. It is not always easy to see on what grounds the conclusions are based nor the reason for introducing the subject of oriental sore which is discussed to some extent. The author's view is that knowledge of these subjects is most imperfect and that it is of the utmost importance that there should be carried out a co-ordinated investigation in the three zones centred on Pasteur Institutes in Algiers Athens and Baku.

PINHO H. Notícia acerca de 40 casos de kala-azar registados da consulta do pósto anti-zenótico do Pócinho em 1943 [Forty Cases of Kala Azar found by the Anti Malarial Organization at Poelinho Portugal, in 1943.] Seronismo Lisbon. 1944 (Trabalhos originaes-1943) 43-5

NÁJERA ANGULO L. Criterio diagnóstico en la leishmaniosis visceral mediterránea. [Diagnosis of Mediterranean Kala Azar] 52 pp 18 figs. [Bibliography] 1946 Madrid.

In this article the author discusses the various procedures and techniques which have been employed in the diagnosis of kala azar basing his remarks on cases of the infantile disease seen by him in Spain. He concludes that the only reliable criterion is the discovery of the parasite itself by puncture of a lymphatic gland the later ones being undertaken only when the earlier ones have failed. He again refers to the presence of his supposed schizogony forms of the parasite in the bone marrow believing that the leishmania in other situations are merely phagocytosed organisms destined to destruction. Actually the article gives no new information of importance.

COOPER G R., REIN C. R. & BEARD J W. Electrophoretic Analysis of Kala-azar Human Serum. Hypergammaglobulinemia associated with Seronegative Reactions for Syphilis. Proc. Soc. Exper Biol & Med 1946 Feb v 61 No 2, 179-83 1 fig [27 refs.]

The electrophoretic patterns of 2 human kala-azar sera revealed the presence in high concentration of a unique abnormal component migrating with the γ globulin of the slowest mobility. The kala-azar sera, negative to serological tests

for syphilis provide instances which show that the presence of hyperproteinemia, hyperglobulinemia or hypergammaglobulinemia cannot be used to prove or disprove the specificity of positive serologic reactions for syphilis.

SAGHER, F. Activation of an Originally Negative Intracutaneous Leishmania Vaccine Reaction. *Acta Med Orientalia (Palestine & Near East Med. J.)* 1946 Mar v 5 No 3 82-5 2 figs.

In the vast majority of cases of cutaneous leishmaniasis, as shown by DOSTROVSKI the injection into the skin of a leishmania vaccine containing 100 000 culture forms of the parasite in 0.1 cc. is followed by a positive reaction characterized by redness over an area 3 cc. in diameter and a central papule. In certain cases which show little tendency to spontaneous healing and which prove very resistant to treatment the reaction is negative. These are often relapse cases, in which a lupus-like condition commences in the margins of an apparently healed sore. In a case described in this paper practically the whole of the right cheek became involved. Treatment by X-rays on a number of occasions failed to induce healing. The skin reaction at this time was negative to vaccines prepared from Palestine and Baghdad strains of leishmania. Treatment with grenz-ray was then given, with the result that healing commenced. At the same time the skin reaction became slightly positive. Complete cure eventually resulted after a period of three years. When healing was complete the skin reaction was strongly positive to both vaccines. The author considers it possible that the failure of such cases as the one described, to show any tendency to spontaneous recovery is due to lack of development of antibody and that it is the lack of this antibody which causes the skin reaction to be negative. With development of antibody healing commences and the reaction becomes positive. On the other hand, the reaction may be due to an increased allergy or hypersensitivity having no relation to immunity. In either case it is not clear how the institution of treatment by grenz-ray could bring this about.

BOSE, A. N., GHOSH, T. N. MITRA, S. V. & DATTA, S. On the Toxicity of some Organic Antimonial Drugs used for the Treatment of Kala Azar. *Indian Med. Gaz.* 1946, Jan. v 81 No 1 13-16.

It is well known that organic antimonials employed in the treatment of kala azar vary considerably in toxicity from batch to batch. This is particularly the case with derivatives of β -aminophenylstibinic acid such as urea stibamine (the exact composition of which is still uncertain) the diethylamine salt (neostibosan) the triisopropylamine salt and others. With a view to throwing light on these variations in toxicity a number of different batches of these preparations were studied from the point of view of their total antimony content and the various combinations in which this antimony was present. At the same time toxicity tests were carried out in mice. It was found that though the toxicity of urea stibamine generally increased with a rising antimony content, it was clear that this was not the sole cause as certain samples with high antimony content were less toxic than others with a lower content. An explanation was found in the presence of antimonious acid. If the ratio of antimony present as antimonious acid to that present in pentavalent organic combination exceeds 1:26 there occurs a definite increase in toxicity. If care is taken, in the preparation of urea stibamine to keep the ratio low it will satisfy much higher toxicity limits than those at present accepted (namely 200-225 mgm./kgm. intravenously). As regards the other compounds studied, the di-ethylamine, and the iso-propylamine salts, their toxicity depends largely

Leishmaniasis

Vol 43 No. 11]

on impurities in the amines employed in their preparation There was also some indication that the toxicity of the di-ethylamine salt could be reduced by incorporating a minute trace of a suitable reducing agent

DUTTA, N K MUKERJI B & SEKAR C C The Possibility of using Pigeons in Toxicity Determinations of Organic Antimony Compounds. *Quart J Pharm & Pharmacol* 1946 Apr-June v 19 No 2 89-96 2 figs

Since white rats and mice are not freely available in all parts of India the use of pigeons has been suggested for determining the toxicity of organic compounds of arsenic and antimony. The common Indian pigeon (*Columba livia intermedia*) is found all over the country and can be obtained at reasonable cost. It is easily handled and is not exacting in its requirements. These birds kept under good conditions in groups of four were used in conjunction with chemical tests for the assay of urea stibamine. A freshly prepared 4 per cent aqueous solution was given into a wing vein. Not less than twenty pigeons were inoculated at a time and the period of observation was one week. For the purpose of comparison parallel toxicity tests on the same batch of drug were carried out with mice. From analysis of the results obtained in the two series of tests it was concluded that under the conditions employed the use of pigeons for bio-assay was justified

OASTLER E. G & FIDLER H. K. Cerebral Lesions produced in Healthy Dogs by the Intravenous Injection of 4,4-Diamidino Stilbene. *Trans Roy Soc Trop Med & Hyg* 1946 June v 39 No 6 533-8 5 figs. (4 on 1 pl.)

In this paper are described certain lesions of the central nervous systems in dogs following the intravenous injection of freshly prepared solutions of stilbamidine. The experiments were undertaken because of observations made on cases of kala azar treated with old solutions of stilbamidine which had been exposed to light. A number of dogs treated with the same old solutions showed pathological lesions in liver and kidneys. It is now well known that under the above conditions stilbamidine solutions undergo photochemical change [this *Bulletin* 1943 v 40 23 683 684 1944 v 41 196 1945 v 42 18]. When freshly prepared solutions were administered to 10 other dogs significant pathological lesions occurred only in the c.n.s. and were associated with definite clinical signs especially spasticity. The lesions described in the text included infiltration and thickening of the walls of blood vessels myelin degeneration softening inflammation of the meninges as well as haemorrhage and thrombosis. Nervous disturbances have previously been described in man and animals treated with members of the diamidine series [this *Bulletin* 1940 v 37 404 1942 v 39 748 1944 v 41 273]. The dosage schedule for the dogs was 1 1.5 and 2 mgm. per kilo. of body weight given intravenously each day during the first second and third weeks respectively. From 4 to 21 injections were given in the series before the animals died or were killed. Five of them showed clinical signs indicative of damage to the c.n.s. which was verified *post mortem* but its degree was apparently unrelated to the amount of drug given. Three other animals had no brain lesions while in the liver of one two the damage was microscopic. Foci of necrosis occurred in the liver of one dog, and others had slight fatty degeneration of the kidneys. The cerebral lesions were believed to result from vascular spasm or anoxia and in view of the neuropathic signs noted in human cases after treatment with diamidines this probably does not represent a special susceptibility in the case of dogs.

MUKERJEE S. Penicillin for Isolation of Bacteria Free Culture of *Leishmania* Parasites. *Ann Biochem & Exper Med Calcutta*. 1945 v 5 No. 3 95-6

The author has shown that the flagellates in cultures of *leishmania*, both in liquid and on solid blood media are highly resistant to penicillin though with increase in the concentration of penicillin from 100 to 1 000 units per cc. a decreasing percentage of flagellates survive. Nevertheless the surviving flagellates in the media containing the highest concentration of penicillin are able to give rich cultures when introduced into penicillin-free media. Advantage is taken of this resistance to penicillin in the isolation of *Leishmania tropica* from contaminated skin lesions. The contaminated material from the lesion is inoculated into liquid or solid medium containing penicillin (200 to 1,000 units per cc.) After a few days incubation at 22°C. subculture into penicillin free medium is made or if staphylococci are still present once more in a penicillin medium.

DOSTROVSKY A. & SAGHER, F. Generalized Recurrence in *Leishmaniasis* (Oriental Sore). Report of a Case with 110 Lesions. *Ann Trop Med & Parasit* 1945 Oct 10 v 39 No 2 98-100 4 figs. on 1 pl.

The case described is that of a girl of 10 years of age from Aleppo who suffered from multiple skin lesions due to *leishmania* infection. These lesions healed in four months, but about four months later fresh lesions began to develop at the original foci, and continued to do so till complete relapse of the original condition had occurred. In the course of time certain lesions showed a tendency to spread to new foci by way of the lymphatics. When the patient was seen by the authors after the disease had persisted for four years there were 110 lesions some of the larger of which were due to confluence of a number of smaller ones. The distribution was on the face and limbs including the gluteal region. Some were present also on the inner mucous surface of the lower lip. The lesions were of a lupoid, serpiginous, gummatous and ulcerative type. The diagnosis was established by the discovery of *leishmania* in smears, and by culture from the lesions. The author concludes that in this case there had been a complete breakdown of the usual cutaneous immunity. As a rule, in the few cases which relapse, this is a local phenomenon involving only one or two of the many healed foci of infection.

PISSÓA, S. B. & BARRETO M. P. Contribuição para o estudo da imunidade da leishmaniose tegumentar americana [Immunity in S. American Cutaneous *Leishmaniasis*]. Reprinted from *I Reunião Anual dos Dermatologistas Brasileiros* Rio de Janeiro 26-28 Sept. 1944 1945 137-51 (28 refs)

In discussing immunity in S. American cutaneous *leishmaniasis* the authors show that after recovery, the majority of infected individuals possess a solid immunity. Apart from the fact that as a rule secondary or relapse lesions do not develop this is supported by the negative Montenegro reaction and the failure to produce infection by inoculation of living cultures in recovered individuals. In some persons however at various times after healing of the primary sore secondary lesions appear on the skin or mucosae. These are the result of metastatic distribution of parasites which in certain cases, have been shown to survive even in the cicatrized lesions. Occasionally there exists a natural immunity as shown by one or two individuals of a family who alone

Vol 43 No 11] *Fever of the Typhus Group*

fail to acquire the disease though they are as numerous as in some other places. In some many years as other members who became infected with the disease. Experiments on monkeys show that 100 per cent become infected from type develops illustrating a partial natural immunity.

Experiments on monkeys show that 100 per cent become infected from inoculation of living cultures. Vaccination of six monkeys with a vaccine of killed flagellates protected four against infection with subsequently inoculated living flagellates. When these experiments were extended to human beings of 444 vaccinated individuals 12 (2.7 per cent) subsequently acquired the disease in an endemic focus while of 683 unvaccinated individuals 108 (15.6 per cent) became infected in the same period. In the vaccinated individuals who were immune the Montenegro reaction was negative as in the case of persons who were immune after recovery from the naturally acquired disease. It is concluded that vaccination can play an important part in the prophylaxis of American cutaneous leishmaniasis.

FEVERS OF THE TYPHUS GROUP

ANGSTEIN L. Problems of Nomenclature of certain Pathogenic Rickettsiae and Rickettsial Diseases. *Texas Reports on Biol & Med* 1946 v 4 No 2 111-18. [12 refs]

ANGSTEIN L. Problems of Nomenclature of the Pathogenic and Rickettsial Diseases. Texas Reports on Zoonoses, No 2 111-18. [12 refs]

The author stresses the need for an agreed nomenclature of the pathogenic rickettsiae and of the diseases caused by them. He mentions some of the attempts that have been made to formulate a satisfactory nomenclature and makes a proposal that a technical Inter American committee should be set up to make recommendations on the subject in accordance with the accepted international rules of botanical nomenclature. He rightly lays emphasis on the importance of simplicity and usefulness in connexion with the choice of names. He admits that the knowledge of the biological properties of the rickettsiae is incomplete and that no final judgment can yet be passed on the exact position of the pathogenic rickettsiae in the system of microbiology. He states that only one of the many names applied to these organisms has received universal acceptance, viz *Rickettsia prowazeki* Rocha Lima, 1916. He favours the use of the following names: Louse-borne typhus fever - *fever* *dermatocentrozonus*; Rocky Mountain spotted fever - *Rickettsia tsutsugamushi*; flea-borne typhus fever - *Rickettsia tsutsugamushi* disease; and *Rickettsia tsutsugamushi* rickettsia Wolbach 1919. He expresses a dogmatic opinion regarding the most suitable names for the organisms causing flea borne typhus and boutonneuse fever.

[A generally accepted nomenclature for the fevers of the typhus group and their causative organisms is badly needed but a committee attempting to deal with the matter would encounter a serious difficulty at the very outset. A primary requirement of scientific nomenclature is that each name must apply to something that can be clearly identified and differentiated from all other objects or conditions. Seeing that pronounced differences of opinion still exist among experts with regard to the relationships of the different fevers of the typhus group it seems necessary to fall back on provisional names which

ANIGSTEIN, L. Problems of Nomenclature of certain Pathogenic Rickettsiae and Rickettsial Diseases. *Texas Reports on Biol & Med* 1946 v 4 No 2 111-18 [12 refs.]

The author stresses the need for an agreed nomenclature of the pathogenic rickettsiae and of the diseases caused by them. He mentions some of the attempts that have been made to formulate a satisfactory nomenclature and makes a proposal that a technical Inter American committee should be set up to make recommendations on the subject in accordance with the accepted international rules of botanical nomenclature. He rightly lays emphasis on the importance of simplicity and usefulness in connexion with the choice of names. He admits that the knowledge of the biological properties of the rickettsiae is incomplete and that no final judgment can yet be passed on the exact position of the pathogenic rickettsiae in the system of microbiology. He states that only one of the many names applied to these organisms has received universal acceptance viz *Rickettsia prowazekii* Rocha Lima 1916. He favours the use of the following names: Louse-borne typhus fever *fever*, *borne typhus fever*, Rocky Mountain spotted fever *Dermacentor*, *rickettsii* Wollbach 1919 *tsutsugamushi* disease and *Rickettsia tsutsugamushi* Hayashi 1920 but does not express a dogmatic opinion regarding the most suitable names for the organisms causing flea borne typhus and boutonneuse fever.

[A generally accepted nomenclature for the fevers of the typhus group and their causative organisms is badly needed but a committee attempting to deal with the matter would encounter a serious difficulty at the very outset. A primary requirement of scientific nomenclature is that each name must apply to something that can be clearly identified and differentiated from all other objects or conditions. Seeing that pronounced differences of opinion still exist among experts with regard to the relationships of the different fevers of the typhus group it seems necessary to fall back on provisional names,

[November 1948]

ought to convey helpful suggestions of the chief features of the diseases in so far as these are known at the present time.

Two of the names considered most suitable by the author—louse-borne typhus and flea-borne typhus—comply with these requirements and there seems to be no valid objection to the extension of the same type of nomenclature to the mite-borne and tick-borne fevers of the group. Clinically and pathologically, these diseases are generally agreed to be closely related to classical typhus, and their association with mites and ticks is universally recognized.

Some workers believe that there are two or more tick-borne typhus fevers, so it would be desirable to add the name of the locality of occurrence or of the type of the disease (Rocky Mountain, boutonneuse etc.)

Each of the causative organisms of the different typhus fevers could be referred to as the rickettsia of the fever concerned.

The use of this system of nomenclature would not imply adhesion to one or other of the conflicting views regarding the antigenic relationships of the causative organisms. The name typhus fever of unknown or doubtful vector would cover the cases in which no satisfactory evidence can be obtained to incriminate any one vector and in such cases the addition of the name of the serological type (O129 OLA OVS or indeterminate) would be helpful.

In the interests of brevity the word "bore" could be dropped without fear of causing misunderstanding.

The rules of botanical nomenclature are not applicable to the names of diseases, and the time is not ripe for a final pronouncement on the names of the rickettsiae of the typhus fevers.]

MACCHIARELLO A. CIFUENTES T. O. & OVALLE H. Estudios sobre tifo exantemático. Influencia de la administración parenteral de altas dosis de ácido ascórbico en la evolución del tifo Europeo (no orquítico) experimental del cobayo. (The Effect of Parenteral Administration of Large Doses of Ascorbic Acid on the Evolution of Experimental European (Non-Orchitic) Typhus in Guinea-pigs.) Rev Chilena de Hig. y Med. Preventiva 1945 Sept. 7 No. 3 175-87 1 fig. [11 refs.] English summary

The authors report the results of experiments designed to show whether large doses of vitamin C have a preventive or curative action in guinea-pigs infected with typhus rickettsiae.

Ten guinea-pigs were given daily doses of ascorbic acid ranging from 50 to 1000 mgm by subcutaneous or intramuscular injection, starting from the day on which they were inoculated with epidemic typhus rickettsiae. These animals, and 15 controls infected in the same way were given the usual vegetable diet. The effects observed in detail they can be summarized as follows—(1) pronounced, but temporary antipyretic action proportional to the doses given (2) diminution in the number of brain nodules (3) a tonic action shown by hypothermia, or even death (4) an absence of anti-rickettsial action, as shown by the normal duration of the incubation period, the return of the fever curve to the usual type after cessation of the injections and the retention of the virulence of the infecting rickettsiae.

It is also pointed out that in Chile the morbidity of typhus fever is highest during the spring and summer when the diet of the people is richest in vitamin C.

John W. D. Megaw

MACCHIARELLO A CUFUENTES O & OVALLE H Estudios sobre tifo exantemático VI Influencia de la vitamina C sobre la evolución de la curva en el tifo exantemático humano y experimental del cobayo [The Effect of Vitamin C on the Fever Curve of Exanthematic Typhus in Man and Experimental Guinea-pigs.] *Rev Chilena de Hig y Med Preventiva* 1945 Sept v 7 No 3 189-96 1 fig English summary

Eight guinea-pigs were given daily subcutaneous injections of ascorbic acid in doses of 100 to 1 000 mgm starting from the first day of fever resulting from inoculation with epidemic typhus rickettsiae. The effects were similar to those described in the preceding paper except that the typhus nodules were more abundant. The two guinea-pigs that received doses of 1 000 mgm died after two and six days and no cause of death other than the toxic action of the drug could be detected.

Intravenous injections of ascorbic acid were given to 23 epidemic typhus patients in daily doses of 100 to 600 mgm. The average response was a fall of the temperature by 0.5 to 1.0°C. In a quarter of the cases the duration of the fever was reduced to 10-12 days and in one-third of the patients there was an apparent improvement in the general condition but there were five deaths including two in cases in which the treatment had been started on the 3rd and 5th days.

The action of the drug was regarded as being similar to that of any effective antipyretic. In one case rickettsiae were isolated from the patient's blood after the temperature had fallen to normal.

John W D Megaw

MACCHIARELLO A & OVALLE H Estudios sobre tifo exantemático VII Estudio experimental acerca de la acción *in vitro* del ácido ascórbico sobre el virus del tifo exantemático epidémico (Europeo) [An Experimental Study of the Action *In Vitro* of Ascorbic Acid on the Rickettsiae of Epidemic Typhus (European)] *Rev Chilena de Hig y Med Preventiva* 1945 Sept. v 7 No 3 197-209 1 fig English summary

In a series of controlled experiments various suspensions containing the rickettsiae of epidemic typhus were kept in contact with acid and neutral solutions of ascorbic acid for 5 to 15 minutes at a temperature of 37°C and then used to inoculate guinea-pigs. The only inhibiting effects observed were with the acid suspensions and it was concluded that the acidity of the inoculum was responsible for these so that there was no evidence of any anti-rickettsial action *in vitro* by vitamin C. Even if there should have been any anti-rickettsial action this must have been transitory and reversible it did not affect the viability or virulence of the organisms. For details of the experiments the original paper must be consulted.

DAVIS D E & POLLARD M Prevalence of Typhus Complement Fixing Antibodies in Human Serum in San Antonio, Tex. *Pub Health Rep Wash* 1946 June 21 v 61 No 25 923-31

The authors carried out complement fixation tests on the sera of 4,219 persons engaged in food-handling in San Antonio, Texas. Wassermann positive sera were excluded to avoid the possible fallacy due to false positive reactions. The antigen was prepared from the Wilmington strain of murine rickettsiae. Complete fixation with serum diluted 1-10 was regarded as indicating the occurrence at some earlier date of an attack of murine typhus.

The percentages of positive reactions in the various groups of persons tested are shown in the table

	Number tested	Percentage found positive
Whites—Male	582	2.3
	1,085	3.0
Female	920	5.0
	1,540	3.2
Latin American—Male	114	4.5
	218	4.1
Female		
	4,218	3.5
Total		

Although the authors admit that the persons tested were specially exposed to risk because of their occupation the results are regarded as showing that many cases of murine typhus had not been reported, presumably because they were sub-clinical

McCulloch R. N. Studies in the Control of Scrub Typhus. Med. J. Australia. 1948 May 25 v 1 No 21 717-38 14 figs. (Numerous refs.)

This paper consists for the most part of a report on the introduction and practical application of dibutyl phthalate as a method of controlling scrub typhus among the Australian troops in the recent war. At the end of 1942 information was received from the U.S.A. that dimethyl phthalate was of special value in protecting against the bites of larval mites when applied to half inch bands to all entrances to clothing and to wider bands on the socks. The author who was appointed to study the methods started work at Sydney in March 1943 and continued his investigations in South Australia, Queensland, New Guinea and Borneo.

In early experiments it was found when dimethyl phthalate was rubbed on the clothing using 1.0 to 1.25 cc. for each square foot, bites were prevented for two days but that application in bands four inches wide, using 3.5 cc. per square foot to all entrances to the clothing failed to give protection against bites. The chemical appeared to act by poisoning rather than by repelling the mites which travelled freely on the treated clothing but died after about an hour's contact.

Dibutyl phthalate was found by test to be even more effective and as it could be made available in larger quantities it was used in the further tests. DDT had also been tested but sets of clothing treated by sprinkling with four ounces of petrol or six ounces of kerosene containing 5.0 gm. in solution, or by dusting with 7.5 gm. of the powder ceased to be protective after the clothes had been washed four times in soap and running water whereas one ounce of dibutyl phthalate rubbed into the clothing remained protective after eight washings in the same way.

The efficacy of various methods of treating cloth was tested by applying the larval mites to squares of the treated fabric mounted on three-ply boards and finding the time that elapsed before the mites ceased to move. Full details are given of numerous experiments. In New Guinea it was found that when larvae of *Schöngastia blattarum* or *S. pusilla* were applied to cloth treated with

Fever of the Typhus Group

Vol 43 No 11]

dibutyl phthalate at a rate corresponding to one ounce for each set of field clothing all movement was arrested within a maximum period of about half an hour even after the cloth had been washed up to eight times with soap and running water in the manner available to troops in the field. The results were equally satisfactory whether the application was made by hand rubbing or by sprinkling with emulsions or with mixtures of the chemical and alcohol Laundry washing involving two periods of washing for ten minutes with soap solution at 135°F and three machine rinsings totalling 15 minutes caused an appreciable diminution in the toxic effect so that clothing washed twice in this way was no longer protective. These tests were made with cotton clothing woollen cloth treated in the same way ceased to be protective after three to seven washings in soap and running water when vigorous rubbing formed part of the procedure but when the orthodox method of squeezing was employed the protective effect persisted as well as it did in the case of cotton cloth.

In the numerous conditions in which the tests were carried out there was no evidence of a breakdown in the protection afforded except in the case of woollen socks for which more frequent treatments were found desirable.

In some of the tests a few larvae of *Schöngastia parva* *Trombicula minor* *T. Fletcheri* (now regarded as a synonym of *T. akamushi*) and *T. hatori* were included all of these seemed to be fully susceptible but some species of *Gumtherrana* and *Aconitacarus* remained active twice as long.

In tests carried out in Queensland *T. minor* was found capable of prolonged survival on treated fabrics after four or five washings.

The standard method of treating service clothing in field conditions was to supply each man with one ounce of dibutyl phthalate for each set of clothing. The fluid was poured into an open tin a little at a time was taken up by the finger tips of one hand spread over the palmar surfaces of both hands and smeared on the clothing. About 75 applications of this kind could be made from one ounce in such a way as to make a light uniform smear over the shirt trousers and socks. Fortnightly treatments were regarded as affording reliable protection even in severe conditions of wetting with rain and sweat and the protection persisted after washing six or seven times with soap and water. Treated clothing if stored unused and without washing remained fully protective for at least two months.

The fluid was not irritating to the skin except over the scrotum even when applied directly but when it was used as a mosquito repellent great care had to be taken to prevent entry into the eyes.

In some cases it was found advisable to treat the socks once a week. Blankets were treated in the same way once every six months one ounce and a-half was enough for each article.

Benzyl benzoate stated in U.S.A. confidential reports to be an outstanding miticide when applied to clothing was not available for testing. Dimethyl phthalate though more rapidly toxic than dimethyl phthalate to larval mites when applied to clothing not afterwards washed ceased to be protective after one to three washings. Two American mosquito repellents, Staway and Rutgers 612 were found highly protective but ceased to be effective after washing.

Statistics are given to show the striking reduction in the incidence of scrub typhus that resulted from the systematic adoption of the treatment of clothing. In cases of apparent failure it was almost always found that the substance had not been properly applied. Almost complete control of scrub itch was also obtained.

Some notes are given on the habits of larval mites. The most rapid rate of travel on cloth was about 1 in. in four seconds. Boot collecting, though

PLAGUE.

DAVIS D H S Plague in Ngamiland, Bechuanaland Protectorate. Union of South Africa Ann Rep Dept Public Health Year ended 30th June 1945 51-2

In this abbreviated report on the survey, of Ngamiland many interesting points of plague epidemiology are raised and illustrated. As an epidemic of plague it was the largest outbreak in Southern Africa on record and furnished 304 total cases with 158 deaths. It began with the notification however was probably nearer 60 than 60 per cent. of a number of sudden deaths in a population of 15 000 persons. Recognition of the nature of the disease was soon forthcoming and measures were hurriedly adopted to deal with prevention of spread. These were — anti-plague vaccination (presumably with a killed vaccine) recruitment of an anti-rodent staff to engage in bait-spraying application of cyanogen and destruction of vermin quarantine of areas concerned and prohibition of inter-kraal movement. Most of the cases were bubonic but some invariably fatal were septicaemia or pneumonic. There was no doubt that the insect vectors were plague-infected fleas, and most of these were without rodent hosts for much of the epidemic. This fact has special significance in view of the data which are now accumulating on the survival time and transmission potentiality of the plague flea. Moreover this epidemic has the added interest of showing the connexion not only of epidemic with epizootic but also of epidemic with sylvatic plague. The rodent concerned, the multimammate mouse belongs to the class of the semi domestic mice. There was an unusually favourable season for increase in the population of these small rodents, which synchronized with the peak of a secondary plague epizootic in them (from a primary epizootic in gerbils) and with flooding of swamp rodent burrows. The consequent over-crowding of the mice and food shortage sent the rodent population to the human habitations the villages and kraals, to get grain and other food. With the onset of warmer weather in September and October climatic conditions for the spread of plague from infected rodent fleas to man became more favourable and the human epidemic resulted. A series of recommendations applicable to the primitively housed population of Ngamiland, are given and special note is made of the great possibilities of DDT for the control of insect-borne diseases in such a population.

BLANC G & BALTARD M Virulence des déjections de puces pesteuses. [Virulence of Flea-Flea Dejects.] Ann. Inst. Pasteur 1946 May-June 72 Nos 5/6 495-9 1 fig

Originally, several thousand fleas were fed on plague-infected guinea-pigs and once these fleas were definitely infected they were placed in a flea-house to which only fresh fleas were afterwards added. These fresh fleas usually became infected by the second day. Breeding took place and litters of new fleas became infected on the animals contaminated by their predecessors. The process had gone on for 14 years when flea dejects were removed, for the purpose of these experiments from the hair of a white rat which had been placed in the flea-house. This rat was dead by the following evening of proved plague. The dejects were sealed in an ampoule and kept in the dark at room temperature. Tests of this material by subcutaneous inoculation of guinea-pigs proved that it was still capable of causing plague after 24 hours 122 days 180 days 316 days 1 year and 18 months. The significance of these experiments is obvious. It would seem probable that the virulence of dejects in burrows can be long maintained.

and that this would suffice to provide one explanation of the endemicity of plague in rodents. Still further deductions are permissible which would extend infectivity via the faeces not only to the human flea but also to the louse especially as it has been shown that mice can be infected through mucous membranes by dejecta of *Pulex irritans* from human plague habitations.

AMOEBIASIS AND INTESTINAL PROTOZOAL INFECTIONS

WATSON J M The Effect of Urine on *Entamoeba histolytica* *Ann Trop Med & Parasit* 1945 Oct 10 v 39 No 2, 101-16 1 fig [31 refs.]

The author has investigated the action of urine on *E. histolytica* from the point of view of the possibilities of urinary amoebiasis. He has shown that at the temperature of the human body urine is highly lethal to the amoebae which are quite unable to live in it. The lethal effect however develops slowly the first signs being noticeable in two hours. Exposure to urine of various concentrations either alone or mixed with faeces at lower temperatures for periods exceeding two or three hours results in a gradual reduction in the numbers of amoebae and loss of motility in those that remain. After 24 hours the majority of the amoebae are degenerate and quite unrecognizable. These results emphasize anew the well known rule that in the collection of faecal samples for diagnosis of amoebic infection it is imperative to avoid admixture with urine. Tests were carried out in order to discover the cause of this lethal action. The amoebae were shown to be capable of surviving and multiplying in media with a pH as low as 5.9 while they remain uninjured by still lower pH values for several hours. As regards osmotic pressure the amoebae can live in solutions equivalent to Ringer's solution of from 0.3 to 1.7 times the normal strength. Quite apart from the lethal action of variations in pH or osmotic pressure urine may be toxic on account of two of its constituents namely urea and ammonia both of which killed and disintegrated all amoebae in culture tubes in 48 hours.

From the results of his experiments the author concludes that it must be extremely difficult for *E. histolytica* to establish itself in any part of the urinary tract where it will be continuously immersed in urine. On the other hand, amoebic invasion of the walls of the urinary passages by direct or metastatic extension might occur in such a manner that the amoebae in the wall were not continuously bathed in urine. From such lesions amoebae might from time to time escape into the urinary passages and if rapidly voided before degeneration occurred, give rise to a diagnosis of urinary amoebiasis. Actually however there is no information available regarding the condition of the walls of the urinary passages in the few cases of urinary amoebiasis which appear to be authenticated. [See also the critical review of urinary amoebiasis by the same author this *Bulletin* 1945 v 42 947]

SNELL, A. M. Some Clinical Problems of Amoebiasis. *U.S. Nav Med Bull* 1946 July v 46 No 7 1023-40 2 figs [18 refs.]

The author has written this paper in view of the increased occurrence of amoebiasis in the United States as a result of the return there of men infected overseas. Whilst it contains nothing original the paper consists for the most part of a well-balanced appreciation of the epidemiology pathology clinical picture complications and sequelae diagnosis and treatment

[November 1946]

of amoebiasis. The fundamental diagnosis of the condition by finding the parasite is suitably stressed and the need for tenacity of purpose and for skill in the procedure is mentioned. The ancillary methods of examination are discussed in proper perspective. The remainder of the paper contains brief accounts of four cases of amoebiasis illustrating either of its main features or of the difficulties in its diagnosis when associated with complicating diseases.

[In the reviewer's opinion this paper is an admirable and up-to-date general account of amoebiasis worthy of wide circulation.]

A R D Adams.

Proc Roy Soc Med 1946 July v 39 No 9 541-50 (Sect. of Proctology 9-18) Discussion on the Use of Medicaments in Diseases of the Colon and Rectum. MURGATROYD F HARGREAVES W H LOVIBOND J L SOMERVILL, T H MORGAN C N WRIGHT A D HUNT A H]

Opening the discussion MURGATROYD stated that the drugs commonly used in the treatment of amoebiasis fall into three groups—(1) Ipecacuanha derivatives (emetine hydrochloride and emetine-bismuth-iodide) (2) substituted phenyl arsonates (carbarsone and stovarsol) and (3) iodoxyquinoline compounds (chimofoin and diodoquin). After brief consideration of the treatments in vogue for amoebiasis he stated that the successes achieved had been variously assessed as between 75 and 95 per cent. To understand the failures it is necessary to consider the parasite the patient and the procedure. There is no sound experimental evidence that drug resistance is acquired by the parasite. Whether some amoebae live in the bowel as commensals, or whether all live in the tissues, has not been established. The state and distribution of the drugs in the body is a matter of speculation. In the cat emetine given parenterally is largely excreted in the urine, and fails to cure an *E. histolytica* gut infection. In man it fails to sterilize most of the acute cases, and is particularly poor in this respect in producing cure and thus may be due by the mouth is much more effective in producing cure and thus may be due to its slower absorption by this route and the consequently longer maintenance of an amoebicidal concentration in the tissues. The control of a concomitant bacterial colitis may render an amoebic infection more amenable to successful treatment, but the primary aim should be to sterilize the amoebic infection before such a condition develops.

HARGREAVES spoke of the chronic bed-ridden cases of amoebiasis from Burma seen by him after they had received many emetine injections and other treatments, both overseas and at home. He found the outlook for these distressing cases considerably changed when penicillin was given as it rendered the amoebic dysentery more amenable to specific drugs. Its use with sulphasalicylate concurrently was therefore adopted for such cases, as a preliminary to a combined course of anti-amoebic treatment. Penicillin and sulpha-salicylate treatment was tried for chronic ulcerative colitis in nine cases with satisfactory immediate results, although permanent cures could not be claimed.

LOVIBOND reviewed his clinical impressions of about 1 000 hospital cases of amoebic dysentery in Ceylon, Assam and Burma, and concluded that a continuous sequence of treatment is all-important. EBI and chimofoin enemata are possibly the keystones of treatment and Carbarsone should clear residual cysts.

Howard SOMERVILL, recording his South Indian experience of colonic disease, said of amoebiasis that most of the work of the medical wards seemed to be "clearing up the failures of other doctors by giving continuous courses

of emetine to patients who had already had scores of injections but never more than five or six at one time. He stressed the importance of continuous daily treatment with E.B.I. for at least 12 days and the need for adjuvant treatment with quinoxyl retention enemata in chronic cases. He referred to 10 cases of amoebic disease of the rectum and four of amoebic abscess in the perineum and buttocks in which surgery and emetine treatment were effective. All cases of carcinoma of the rectum and emetine should be examined for amoebae before operation or radium treatment. He related his experience with cases of concurrent bacillary and amoebic dysentery of bacillary dysentery and of tuberculous disease of the colon.

Naughton MORGAN spoke of the difficulties in differential diagnosis of amoebic tumours of the gut and the dangers of operation in undiagnosed amoebiasis or bacillary infection. In discussing the use of sulphasuxidine in the surgery of the rectum and colon he recommended bigger dosages prior to bowel surgery than those originally advocated by POTH.

Dickson WRIGHT listed a number of conditions, including amoebic dysentery which benefit from sterilization of the faeces by suitable sulphonamide therapy and HUNT recorded data showing the reduction in the incidence of peritonitis complicating major intraperitoneal surgery of the colon and rectum after pre-operative sulphasuxidine treatment. A R D Adams

RADNA, R. Sur le traitement de l'amoebiose par l'iodoforme (Deuxième note.) [The Treatment of Amoebiasis with Iodoform.] *Ann Soc. Belge de Méd Trop* 1945 Dec 31 v 25 No 3/4 219-20

The author treated 18 carriers of cysts of *E. histolytica* with iodoform using the technique recommended by CASTELLANI and SCOTT. The iodoform was given in small gelatin capsules each contained in a much larger capsule of sodium bicarbonate.

Each capsule of iodoform contained 0.05 gm. One such capsule was given on the first day of treatment two on the second four on the third and six on the fourth day. The dose of six capsules was continued until the fourteenth day. A second course was given after a month's rest. For the two courses a total dosage of 7.3 gm. was thus administered. Twelve of the patients were free from cysts after 15 days of treatment and 16 after 1 month.

The author points out that the relatively low price of iodoform makes it possible to employ it on a large scale in the sterilization of carriers of *E. histolytica* cysts. H J O D Burke-Gaffney

BRUG S L. Pseudoparasitism of the Human Intestinal Tract. *J Parasitology* 1946 June v 32 No 3 222-4 1 fig [14 refs.]

On one day in four out of thirteen fecal samples from a psychiatric ward, coccidial oöcysts, probably of *Eimeria debilis* were found. The cysts stained red with eosine solution and were apparently dead. Possibly they had been ingested with liver sausage for the preparation of which pigs' bowels may have been used.

November 1948

RELAPSING FEVER AND OTHER SPIROCHAETOSSES.

D'IGNAZIO C. & CODELEONCINI, E. La forma polmonitica della febbre malarica e la polmonite primitiva dermatofila. Nota clinica. [Pneumonia Form of Relapsing Fever and of Typhus.] Boll. Soc. Ital. di Med. e Ig. Trop. (Ser. Entrea) 1945 v. 5 No. 5/8 211-20 English summary (3 lines)

Details are given of four cases selected from a larger number. They are important to note because in all of them the symptoms pointed strongly to a lobar pneumonia of the ordinary pneumococcal type—pain, cough, fever, haemorrhagic sputum and signs of consolidation—but the basic disease was relapsing fever or typhus. Eighteen of the former are mentioned and 12 of the latter. The four detailed were sent to hospital as cases of frank pneumonia and it was the presence of an enlarged liver or spleen, and the failure of sulphonamide drugs to relieve which led to further laboratory examination and the finding of the spirochaete in the one type and of a positive Weil-Felix in high dilution (up to 1:2,560) in the other.

H Harold Scott

D'IGNAZIO C. Schema di terapia delle febbri ricorrenti africane. [The Treatment of African Relapsing Fever.] Boll. Soc. Ital. di Med. e Ig. Trop. (Ser. Entrea) 1945 v. 5 Nos 5/8 17-27 English summary (2 lines)

The author gives his views on the treatment of relapsing fever in Addis Ababa, which is chiefly louse-borne. He uses neosalvarsan, bismuth and stovarsol. [The author refers to neosalvarsan and "salvarsan" indiscriminately.] In the early febrile stage he gives neosalvarsan in fairly large doses (0.6-0.75 gm.) intravenously with, or without, Hepatamin (presumably a liver preparation) as a protective and injected slowly. In the second attack of fever to forestall renal and hepatic lesions he gives first a small dose of 0.1 or 0.15 gm. neosalvarsan to test the patient's tolerance and then returns to the larger dose (0.6 gm.) After the crisis there may be no more attacks, but as a prophylactic 0.3 gm. may be given intravenously and repeated every 3-4 days for 3-4 times. When the patient has had 1.8-2.1 gm. in the first night after the attack, and there has been no relapse, he may be regarded as cured. The author is not an advocate of the still larger doses (0.6 gm.) as recommended by some physicians.

For treatment during the afebrile period the following course is favoured. If begun during the first three days of calm, injections of neosalvarsan should be made intramuscularly on alternate days in doses of 0.2 0.3 0.4 0.5 0.6 and 0.8 gm., the interval between the penultimate and the last dose being 3 days. If administered in the second three days, in view of the early return of fever a larger initial dose is given 0.4 gm. repeating it twice on alternate days then 0.5 gm. repeating thrice. [totalling says the author 2.1 gm. but as stated the total would be 3.2 gm.] He is presumably referring to neosalvarsan, in view of the relatively high dose. Bismuth he uses in doses of 30-40 ccgm. suspended in oil and injected intramuscularly. If desired, it may be given on the days intervening between those for injection of neosalvarsan. Stovarsol per os is useful for children. To the very young he gives 0.25-0.45 gm. daily for 10 or more days. For children "in the second infancy" (7.5-10 years) the dose is 0.5-0.7 gm. daily for the same length of time. For adults during the fever period he gives 1.25-1.5 gm. on two consecutive days and he has obtained cure without further treatment. During the afebrile period he gives 0.75 gm. daily for 7-8 days and claims that he has usually obtained a cure by this means in exceptional cases a longer course is needed.

Yaws

Patients presenting signs of hepatic inadequacy—jaundice epistaxis, petechiae with pain over the liver—are given 50-80 gm of glucose daily and 10-20 units of insulin subcutaneously. If the glucose causes vomiting when taken by mouth it may be given intravenously in 10 per cent. solution 10-20 cc. at a time. For headache the ordinary antineuralgics usually suffice but if it is very severe lumbar puncture may be needed [the quantity of fluid to be with drawn is not stated] for the rheumatic symptoms salicylates may be given by mouth by rectum or by injection and vitamin B intramuscularly or intravenously
H Harold Scott

YAWS

WINDELLE J H REIN C R STERNBERG T H & SHELDON A J Preliminary Report on the Evaluation of Penicillin in the Treatment of Yaws. *Amer J Trop Med* 1946 May v 26 No 3 311-18 1 graph. [10 refs.]

The authors review seven papers on the subject and find that although clinical cure of yaws has resulted even with small doses of penicillin (50 000 to 500 000 Oxford Units) very few cases were observed to attain Kahn or Wassermann sero-negativity

The present work was done in a part of Haiti where syphilis was not prevalent. Three groups of patients were studied the details are set out in the Table below

Approximately 60 per cent in each series were under 17 years of age. The diagnosis of yaws depended on clinical and serological findings. In a check examination in all cases. Considerable efforts were made to follow cases after treatment. In Series A at 3 months 72 per cent. and at 6 months 84 per cent and in Series B and C at 3 months 60 and 66 per cent respectively were re-examined. Observations in all series are to continue for one year

In Series A skin lesions began to dry in 24 hours pain in the joints and plantar and palmar yaws disappeared in 2-3 days. In most cases healing was complete in one month—a few ulcerated primary lesions with bacterial infections had healed by the second month. In Series B and C all lesions had healed in 3 months except three ulcerated primaries [These were probably primary lesions in pre-existing ulcers in these the ulcers are unaffected by anti-yaws chemotherapy]

At 6 months in Series A only two cases showed possible plantar lesions indicating relapse. At 3 months in Series B one case was similarly a possible relapse, and a second might have been re-infected. However no serological relapse preceded these clinical manifestations

Only 3 of the 500 cases had negative Kahn reactions before treatment. In Series A at 3 months after treatment 98 per cent showed reductions in serological titre mostly to a quarter of the initial titre. A number of serological tests including the Quantitative Kahn and Quantitative Kolmer tests were employed and were carried out at the Army Medical School Washington. At the end of 6 months only 17 cases (10 per cent.) in Series A had negative Kahn tests the others showed further slight reductions in titre. Similar results were observed at 3 months in Series B and C in which only one case had a negative Kahn test

Dark field examinations were negative in 8-12 hours after treatment and biopsy material was negative for spirochaetes after 22 hours.

TABLE 1
Age distribution of and total amount of penicillin given to primary and secondary yaws patients

Age groups	5 years and under	6-12 years	13-16 years	17 years and over	Total	Vehicle	Method of administration
Series A— Total dosage penicillin in 4 days	13 1,200,000 O U	60 1,200,000 O U	41 1,200,000 O U	86 1,200,000 O U	200	Penicillin sodium in aqueous solution	Hospitalized. 50 in intramuscular injections of 40,000 O U every 3 hours
Series B— Total dosage penicillin in 2 days	0	74 600,000 O U	27 900,000 O U	50 1,200,000 O U	151	Penicillin calcium in peanut oil with 4.8 per cent. benzocaine by weight	Intra muscular injections at intervals of 24 hours
Series C— Total dosage penicillin in 1 day	0	58 600,000 O U	35 900,000 O U	56 1,200,000 O U	149	Same as Series B	Intra muscular injections at an interval of 10-12 hours
Total number patients	13	100	103	184	500		

Helminthiasis.

Vol. 43 No 11]

No severe toxic reactions were encountered. Half the patients in Series A had a pyrexia (100-104°F) 2-8 hours after treatment started. These had subsided in 10-12 hours. One-fifth of the patients had secondary pyrexia on the 3rd-5th days of treatment.

The authors point out that in active early syphilis similar prompt clinical response would have followed the same treatment but after 6 months 70-80 per cent (some British figures are higher) would have had negative serological tests. It is unlikely that concomitant malaria or syphilis interfered with the serological tests. From the results in Series A in which children and adults received equal doses it would appear that doses in excess of an optimum have no proportionate curative effect. The results of observations for months will be reported later.

HELMINTHIASIS

HERNÁNDEZ MORALES F OLIVER-GONZÁLEZ J & PRATT Caroline K The
Treatment of Schistosomiasis Mansonii with Urea Stibamine (Squibb)
Preliminary Report *Amer J Trop Med* 1946 May 26 No 3 327-9

Encouraged by the results of treating human filariasis with pentavalent antimony compounds in intensive doses [CULBERTSON, ROSE and OLIVER-GONZÁLEZ this *Bulletin* 1946 v 43 54 354] the authors have used urea stibamine (Squibb) in the treatment of 14 cases of schistosomiasis due to *S. mansoni*. The cases chosen were those only who were passing large numbers of live schistosome ova. The patients consisted of seven male and seven female Porto Ricans aged from 12 to 38 years averaging 26 years for men and 21 for women. Accurate clinical records were kept. Only one-third of the patients showed symptoms referable to schistosomiasis.

Three daily intravenous doses were given after a small initial dose of 50 to 75 mgm. was given to detect susceptibility. Thereafter dosage was gradually increased to maximum tolerance.

The amount of the drug tolerated varied from 3.4 gm. to 10.125 gm. The smallest dose was given to a 12 year-old white girl of 73 pounds weight who never tolerated more than 150 mgm. the largest was received by a 29-year-old white male of 131 pounds weight. On an average the men tolerated 13 days throughout 16 days and the women 6-69 gm. throughout 13 days.

Toxic reactions were immediate or delayed. The former included flushing, facial oedema, hoarseness, dyspnoea, tachycardia, abdominal pain, nausea, vomiting, conjunctival congestion and a semi-shock-like condition. Delayed symptoms were generally milder. One death occurred on the 9th day of treatment in a woman who had received a total of 5.03 gm. of the drug.

In nine cases white blood corpuscles fell temporarily to about 3 000 per cmm. Four patients showed traces of albumin and casts during treatment. At the end of treatment 10 patients still showed ova. After one, two, three and four months 12 patients had completely negative stools. The remaining patient, who only received 3.4 gm. of the drug was still passing ova 60 days after treatment. The authors consider that the true evaluation of the drug can only be made after examinations through longer periods of time than the four months recorded but they find the results encouraging. ANDERSON J M *Schistosomiasis and its Control in Egypt*. U.S. Nav. Med. Bull. 1946 July v 48, No. 7 977-1010 7 figs. [13 refs.]
This is a general account of the subject, illustrated by admirable photographs.

AVERT J L *The Habitat of the Snail Host of Schistosoma japonicum in the Philippines*. Science 1946 July 5 5
In 1932, TUBANGUI see this Bulletin 1933 v 30 210 reported a fresh-water snail, at present designated as *Schistosomophora quadrasi* (Möllendorff) to be the intermediate host of the causative agent of schistosomiasis in the Philippine archipelago.

S. quadrasi has been reported from eastern Leyte eastern Mindoro north-eastern Mindanao and Samar. The author's observations relate to southern Samar and around Palo Leyte in early 1945. The species is amphibious, but its preference for an aquatic environment is proportional to the temperature. The molluscs were often found as much as four inches above the water surface, on emergent vegetation but in the hotter parts of the day they migrated beneath the surface particularly in the shade of trees and shrubs. They were found principally in shallow quiet water containing much decayed organic matter particularly coconut fronds. The water usually showed a pH of about 6.0. There was often much pollution from human wastes and in one area 38 per cent of the *S. quadrasi* examined contained stages of human schistosomiasis. Five other species of molluscs were found in the same habitats.

NELSON E C & BAYLIS M *Schistosomiasis Japonica—Laboratory Diagnosis*. Bull. U.S. Army Med. Dept. 1946 June v 5 No 6 673-80 5 figs.

The authors found that direct smear zinc sulphate floatation and acid-ether extraction techniques were not entirely suitable for diagnosis of eggs of *S. japonicum* mainly on account of the coated condition of the eggs, which was characteristic of the cases with which they worked. A sedimentation method was therefore devised which proved satisfactory and is designated the continuous floor funnel sedimentation technique.

Five to ten grammes of faeces are thoroughly mixed with 100 cc. of tap water and passed through a 20-mesh screen into the funnel assembly. This consists of a glass funnel with an overflow tube which fits tightly into the funnel outlet and whose upper extremity is a little below the rim of the funnel. Water is run rapidly into the funnel from above through a fine inlet tube with a bent tip which is placed at the top of the overflow. When the water is about to overflow slightly below the top of the overflow. A slow whirlpool is created the rate of flow is reduced to 100 cc. per 5 minutes. A slow whirlpool is created which carries off fine material through the overflow tube while the eggs settle at the bottom of the funnel. Ten minutes of this part of the technique is adequate. The overflow tube is then pulled out and the settled sediment released into a urine glass allowed to settle again and then examined. (It is to be regretted that the illustration of the apparatus cannot be reproduced satisfactorily in this Bulletin.)

FISHBOY H M *A Case in which Eggs of Schistosoma japonicum were demonstrated in Multiple Skin Lesions*. Amer. J. Trop. Med. 1946 May v 28 No. 3 319-28 8 figs

This case relates to a sergeant in the U.S. Army who was stationed on the island of Leyte in the Philippines for about a fortnight in November/December 1944. He had bathed in a slow running stream on the banks of which snails were found.

Helminthiasis

Vol 43 No 11]

About a week after his departure he noted angioneurotic swellings about both eyes which later involved the whole face. This lasted for three days and was accompanied by constitutional symptoms the fever which lasted for two weeks being followed by a dry nocturnal cough persisting for three weeks.

With the cough there developed grouped pruritic papules on the right subchondral wall together with a small evanescent group on the right side of the scrotum. The rash extended slowly towards the left abdominal wall axilla and back apparently in an intercostal-distribution. The lesions consisted of infiltrative groups of shotty papules.

Early in February ova of *S japonicum* were found in the stool. Physical examination was otherwise without significance except for an eosinophilia of 15 per cent.

The author gives a full description of the lesions which were not vesicular being herpetiform only in distribution and grouping which showed a predilection for the 8th intercostal space.

Biopsies of the abdominal wall and back lesions showed inflammatory reactions which included eosinophiles surrounding distorted schistosome ova. The latter were better preserved in the specimen from the back and the con- tained miracidia were well stained. Four photographs and two micro- photographs illustrate the lesions clearly.

Two courses of Fouadin were given each consisting of 40 cc. and lasting for a fortnight. The last new skin lesion containing ova with active miracidia was found ten days after completion of the first course. On the last observation of the patient two weeks after the second course the skin lesions appeared as small white fibrotic papules. The eosinophilia fell to 10 per cent. after the first course and to 9 per cent. after the second. Proctoscopy revealed no schistosome nodules but the stools remained positive for *S japonicum* ova throughout.

The authors point out that whilst portal infiltrations by *S japonicum* have been described and cases of cerebral and pulmonary involvement have been noted no adult worms of this species have been described in these vessels in man. The case under review manifests systemic involvement as well. Whilst the author considers the possibility of embolic skin lesions from a distant adult worm he also believes that such a worm may have been situated in an inter- costal vessel. He refers to the case reported by GARCIA *et al* (this Bulletin 1941 v 38 43) in which *S japonicum* eggs were found in a skin biopsy from a child suffering from a chronic ulcer of the leg.

CARROLL D G Cerebral Involvement in Schistosomiasis japonica Bull
Johns Hopkins Hosp 1946 Apr v 78 219 [Summary taken from
J Amer Med Ass 1946 July 20 v 131 No 12 1023.]

Carroll reports five cases of cerebral involvement in schistosomiasis japonica which occurred among American officers and soldiers between the ages of 20 and 29 years on the island of Leyte in 1944. In all the cases ova of *Schistosoma japonicum* were found in the stools there was a history of exposure and clinical symptoms and laboratory evidence suggestive of schistosomiasis japonica. Four of the patients presented neurologic involvement in the acute stage of the disease and one patient showed neurologic involvement four months after the acute stage. Those in the early stage had an acute onset of drowsiness followed by coma and incontinence. There were signs of pyramidal tract involvement with weakness spasticity and exaggerated deep reflexes. There was moderate eosinophilia. Symptoms improved with therapy. Neuro- logic involvement in the late stage was manifested by jacksonian convulsions.

followed by the development of hemiplegia but without drowsiness, coma or incontinence. The leukocyte count and eosinophil count were normal. There was no improvement with therapy.

CAMERON T W M. **Fish-carried Parasites in Canada.** (1) Parasites carried by Fresh Water Fish. *Canadian J Comp Med* Gardenvale Quebec. 1945 Sept Oct & Nov v 9 Nos 9 10 & 11 245-54 283-8 302-11 7 figs. [17 refs.]

This is a paper of much interest to veterinarians and to comparative pathologists written with Professor Cameron's known clarity and succinctness. It will appeal less to human pathologists and physicians because three only of the many species of helminthic parasites referred to infest man, and of one of these only a single case—and that rather doubtful—is on record. Of the Heterophyidae several species are known to infest domestic cats dogs rabbits, white mice and a number of birds. In the Philippines, recently four different species were found in nine autopsies, and as four of the patients had died from cardiac trouble it was believed that there was some aetiological connexion between them.

The life-histories of *Anophthalmus renatus* and 4 *brans* are described in full and diagrammatically depicted. Each has two intermediate hosts in the case of 4 *renatus* the first is the small *Goniobasis inescens* the cercariae from this attach themselves to the base of the fin of some fresh-water fish (13 are named among them carp dace perch and catfish) shed their tails and penetrate the infested fish is eaten by a mammalian or avian host. In the stools of a man in Ste Anne's Military Hospital Canada were found helminth ova agreeing in appearance with this species.

Another trematode infesting man and also the dog red fox mink, raccoon and cat but not birds, is *Metorchis*. The life-histories of some species of this genus are unknown but that of *M. conjuncus* is fully described. It is closely similar to that of *Opisthorchis* and *Clonorchis* with two intermediate hosts the small *Acanicola* and a fish, the common sucker (*Catostomum commersoni*). Only in places where the sucker is eaten raw does man become infested.

Clinostomum marginatum occasionally infests man. [Another species has been recorded in man in Japan and is the cause of parasitic laryngopharyngitis known as *Halzoun* in the Near East. See this Bulletin 1945 v 42, 396.] The small intermediate host is *Helisoma trivolvis* *macrostomum* "but other related Planorbis snails may also serve as vectors." Its cercaria has a forked tail and encysts on fins or gills or beneath the scales of certain fish, and produces small abscess-like cysts so that man rarely eats it.

Lastly there is a *Dipyllobothrium* closely related to the European *D. latum* but whether the Canadian one is fresh water cercariae or found in pike and perch. Its first intermediate hosts are *D. siculoides* and the plerocercoids are found in pike and perch. It is one of the commonest cestodes in man in eastern Canada and is found also in dogs often and in foxes cats and bears less often. Other tapeworms with fish as intermediate hosts which may be mentioned, are *Ligula tricuspidata* and *Proteocephalus* but these are not infective for man or for domestic animals.

GELEFAND M The Clinical Features of Hookworm Disease Clin Proc Cape Town 1945 Jan.-Mar v 4 No 1 21-9

In this short paper the author discusses some of the still vexed questions of hookworm disease. He points out that the African with hookworm is usually suffering from other parasitic diseases also—malaria schistosomiasis—or from malnutrition or disorders of the liver and that too exclusive a concentration on the diagnosis of hookworm disease on the evidence of ova in the stool, may be disastrous to a patient. The injudicious administration of an anthelmintic may be fatal in a patient seriously ill from another cause. In dimorphic anaemia (which is the common anaemia of Africa) a cause for the iron loss such as hookworm schistosomiasis malaria or dysentery can usually be demonstrated and it is unlikely that the intake of iron in Africa is unduly low though the nutritional factor in anaemia is extremely important. Treatment for hookworm infestation alone is therefore usually insufficient to cure anaemia and, in fact this mixed anaemia is difficult to treat successfully. In the European the matter is usually very different anaemia is slight or absent but abdominal pain and flatulence are common.

The author has not found that increase in appetite is a marked symptom of hookworm disease although so often mentioned in text-books nor is earth-eating peculiar to those with hookworm in spite of common opinion. Earth-eating is practised by many African tribes partly as a result of the belief that it increases fertility partly as a ceremonial but since many of the earths are rich in salts of iron calcium magnesium and sodium there may be a physiological basis for earth-eating.

The author believes that there is some degree of toxæmia in hookworm disease which, in a few cases may be responsible for fever eosinophilia and oedema when these cannot otherwise be explained. Charles W ilcocks

ROGERS A M & DAMON G J Hookworm Infection in American Troops in Assam and Burma. Amer J Med Sci 1946 May v 211 No 5 531-8

Differing from the traditional picture of hookworm disease the prominent features in 50 consecutive cases in combat troops in North Burma were gastrointestinal symptoms of abrupt onset and lack of anaemia. There were nausea and vomiting with abdominal pain, usually epigastric arising immediately after meals and not relieved by food. Diarrhoea was a prominent sign but blood pus and mucus were not found in the stools. By questioning a history of ground itch was obtained from a quarter of the patients and a history of respiratory symptoms from 70 per cent. but the value of these histories is doubtful. All the patients had lost some weight ranging from 10 to 40 lb but loss of weight was common among all combat troops in Burma. Some patients had a low-grade fever and a few had attacks of urticaria. A striking feature of the infection was the degree of eosinophilia, the discovery of which led in many instances to the examination of the stools. The maximum eosinophilia was 70 per cent with a total leucocyte count of 41 000 per cmm. but the more usual finding was eosinophilia of 40 per cent. with a total count of about 15 000 leucocytes. The earliest time for appearance of eosinophilia after the suspected date of infection was 30 days and the eosinophilia persisted to a diminished degree for weeks and months despite frequent vermifuge treatment. Anaemia was neither marked nor constant. Direct examination of the stool revealed initially only 20 per cent of the infections but by repeated direct examinations it was possible to establish the diagnosis in a little more than half the patients. The zinc sulphate flotation-centrifugation method increased the number of positive findings four fold, and

[November 1948]

proved a rapid and efficient means of finding eggs in the stool in all cases the diagnosis was confirmed by the finding of eggs by one or other of these methods. The routine treatment consisted of 3 cc. of tetrachlorethylene, given in the morning after a fat free supper followed by a magnesium sulphate purge on the previous evening. A second purge was given 2 hours after the vermifuge. If treatment failed, it was repeated after an interval of 3 weeks. Sometimes carbon tetrachloride or hexyresorcinol was used. One week or more after treatment the stools were re-examined. 20 per cent of the patients still showed eggs although on the average they had been treated twice.

The anorexia, vomiting and diarrhoea were most readily relieved by treatment while the cramping pain after meals was the slowest symptom to disappear and the one which persisted in those who were unimproved. It should be pointed out that not all the patients showed the acute syndrome described, and in fact many asymptomatic infections were discovered by the routine examination of the stools of patients admitted to hospital for some other condition.

F Murgstroyd

STUBENBORD W & ALLEN R F Hookworm Disease in Infants. Report of Two Fatal Cases. *U.S. Nav Med Bull* 1946 June v 46 No 6 915-17

Hookworm disease is rare in infants under one year of age partly because they do not often come into contact with infected soil. The authors record two cases from Guam in which massive infection was present in such infants. In the first infant moribund on arrival at hospital 300-400 adult *Angiostrongylus duodenalis* were present in the intestine the child was anaemic and there was fluid in the pleural and abdominal cavities. In the second (dead on arrival at hospital) there were several hundreds of *A. duodenalis* many haemorrhagic areas in the mucosa of the small intestine, and extreme anaemia.

Charles Wilcocks

SCOTT J A Simplified Quantitative Methods for Hookworm Control Programs. *Amer J Trop Med* 1948 May v 28 No 3 331-7 1 fig

The final answer to the problem of the control of hookworm disease is improvement in environmental sanitation. In Georgia, sanitation programmes have not yet reached the families most affected and are unlikely to do so for many years. Interim measures are therefore necessary. The public health authorities have aimed at treating the most heavily infected members of the community with the objects of obtaining the maximum reduction in the source of infection and of relieving the symptoms in those most affected.

It is now generally agreed that the pathogenicity of hookworms is fundamentally based on their blood letting activities that anaemia is the primary symptom and that all other manifestations are secondary to it. The extent to which the severity of anaemia is related to the intensity of hookworm infection is often obscured however by a nutritional factor. Apparently most well nourished persons have enough immunity to prevent the establishment in the intestine of hookworms in numbers sufficient to cause appreciable anaemia. In certain states of malnutrition this protective mechanism is weakened and large numbers of worms become established. Moreover this nutritional imbalance may of itself cause anaemia. Hookworm disease is then primarily the result of the additional drain which the worms place upon a hemopoietic system already nearing if not past its maximum limit of compensatory reaction. In evaluating the seriousness of hookworm disease there are two factors to be considered. The first is a determination of the degree of anaemia

Helminthiasis

Vol 43 No 11]

which can be accurately done by the use of a hemoglobinometer or approximately estimated from the clinical signs. The second is a necessity for determining what portion of the anemic condition is due to the basic state of malnutrition and what portion to the superimposed hookworm infection. HILL and ANDREWS in this *Bulletin* 1943 v 40 324] showed that in Georgia no measurable depression of the average hemoglobin reading was associated with hookworm egg counts of less than 2,500 per cc [the figure corrected for the consistency of the stools was 5 000 per cc]. Above this point however a progressive drop in the hemoglobin reading was correlated with the size of the egg count. From these data it was concluded that in Georgia all of the cases of hookworm disease would be found in the group whose counts were above 2 500 eggs per cc. In practice the order of making these determinations is reversed.

In annual examinations of the schoolchildren the clinically grossly anaemic are selected. The border line cases are checked by haemoglobin examination. egg counts are made on all anaemic children. The families of children with more than 2,500 eggs per cc of stool are visited and those found infected are treated.

There are limitations to the accuracy of this method of selection and further it involved the use of statistical methods which are not simple enough for general application in a health programme. In this paper a modification of this procedure is described.

The data are based on the examination of specimens collected from rural, white families by a visiting nurse. These families were chosen at random from over the whole country except for the fact that obviously well-to-do families were not included. Specimens were examined by a salt flotation method and the positives were re-examined by egg count using the technique as modified by Stoll and Hausheer.

After some necessary adjustments have been made owing to the fact that it was not possible to do egg counts in every case in which the flotation method showed eggs the data are arranged as in the example given below. [While the adjustments that were made would satisfy most statisticians it seems that they could have been obviated by the collection of larger samples of stool in every case.]

Hookworm infection in Brantley County Georgia in 1942

Age Group	No of persons examined	Percent. infected with hookworm*	Percent. positive by egg count†	Percent. of suspected cases of hookworm disease ‡
0-4	160	49.4	45.6	23.4
5-19	514	67.7	63.8	32.6
20+	150	46.7	38.2	11.3

* Per cent. positive by flotation. † With 200 or more eggs per cc.
‡ With 2,500 or more eggs per cc.

This table gives all the important data for the practical use of the health officer but for the use of the statistician for comparison with data in which different levels of significance have been used, further calculations have to be made. The author shows how a normal curve based on the figures of the fourth and fifth columns of the table approximate very closely the normal curve based on the entire series of egg counts and he therefore considers that these two figures will supply sufficient data for most statistical purposes.

- I. ROCHA E SILVA, M & GRASA R. Anaphylaxis-like Reactions produced by *Ascaris* Extracts. I. The Change in Histamine Content and the Coagulability of the Blood in Guinea Pigs and in Dogs. *Arch Surgery* 1946 May v 52 No 5 523-37 4 charts. [Refs. in footnotes.]
- II. — & — II. The Mechanism of the Shock Induced in Dogs. *Ibid* 1946 June v 52 No 6 713-28 6 charts. [Refs. in footnotes.]
- III. — PORTO A & AMBRADE Sylvia O III. The Role played by Leucocytes and Platelets in the Genesis of the Shock. *Ibid.* Aug. v 53 No 2 199-213 3 figs. [20 refs.]

I. In an earlier paper (to be published) the authors studied the mechanism of shock produced by hydatid fluid injected into dogs and concluded that the substance which caused the shock is not precipitated by 5 per cent. trichloroacetic acid, does not dialyze through Cellophane paper and resists boiling for a long time. They obtained a fairly well-purified material which produces profound shock in dogs the shock being indirect, because a second injection produces no appreciable effect (desensitization). In some instances they also found an evanescent incoagulability of the blood (complete incoagulability in some animals) which suggested the liberation of heparin from the tissues into the blood. They found that histamine in the circulating blood of a few animals was increased, but that in most of the animals the histamine in the blood was decreased, although GRASA *et al.* found that histamine was increased in every dog into which hydatid fluid was injected. The authors decided to find out whether nematodes may contain substances which produce shock.

LEROY (*Arch. Internat. de Physiol.* 1910 v 9 276) and EMERY and HERRICK (*Amer. J. Physiol.* 1929 v 91 143) found that extracts of *Ascaris lumbricoides* produce hypotension in dogs. SHIMAMURA and FUJI (*J. Coll. Agric.* 1917 v 4 189) quoted by ESSEX, MARKOWITZ and MANN (*Amer. J. Physiol.* 1931 v 98 18) isolated an albumose peptone which was very toxic to dogs and called this substance askoron. MACHEBOEUR and MANDOUZ (*C. R. Soc. Biol.* 1939 v 130 1032) produced in guinea-pigs with extracts of *A. lumbricoides* emphysema not distinguishable from that produced by anaphylactic shock. The material which did this was soluble in 4 per cent. trichloroacetic acid and in 50 per cent. ethyl alcohol and it was not removed by dialysis. BIER (personal communication to the authors) showed in 1939 that a substance in *A. lumbricoides* produces shock resembling anaphylactic shock in guinea-pigs. The present authors observed that extracts of *A. lumbricoides* produce severe or fatal shock in dogs which has features of anaphylactic shock, namely liver congestion incoagulability of the blood, desensitization after recovery and the appearance of histamine in the blood. The shock is however very severe and nearly all the dogs react violently to a few cubic centimetres of the extract.

The material used for the experiments here described was obtained from *Ascaris lumbricoides* ground in a colloid mill, the pulp obtained being treated with an equal volume of 10 per cent. trichloroacetic acid for 2 hours at room temperature and then left overnight in the refrigerator. The opalescent fluid thus obtained was dialysed through cellophane for at least 48 hours until it was freed from trichloroacetic acid. The pH was then adjusted to neutrality with sodium carbonate and the fluid was used. For details of the further purification of this material the paper itself must be consulted. The tests done suggested that the substance causing shock in dogs is not a protein but a proteose of large molecular weight. A glycogen fraction was also prepared, which was apparently related to the polysaccharide prepared from *A. lumbricoides* by CAMPBELL (*J. Infect. Dis.* 1936 v 59 266). Antithrombin assays

of the blood of the dogs were done with a solution of human prothrombin prepared by the method of QUICK (*Amer J Physiol* 1936 v 116 535)

For details of the experiments done and for the authors' comments upon them the paper itself must be consulted. The authors found that deproteinized and dialysed extracts of *A. lumbricoides* produce a severe form of shock in dogs accompanied by enormous engorgement of the liver, drastic reduction of the liver histamine, increased histamine in the blood, the appearance of an antithrombin (heparin) factor in the circulating blood, and desensitization. The main increase of blood histamine occurred in the portal vein six times higher than that in the femoral vein. Crude extracts of *A. lumbricoides* produced massive emphysema in guinea pigs and death in a few minutes. In a few guinea pigs increase of the blood histamine was observed.

The authors discuss the allergic nature of this anaphylaxis-like reaction. Most of the dogs used had heavy infections with intestinal hookworms; injection of *Ascaris* extracts produced skin reactions so that it is possible that most of the dogs in Brazil are sensitized by intestinal nematodes and that thus sensitization is allergic rather than anaphylactic. The authors emphasize their view that a distinction cannot be drawn between allergy and experimental anaphylaxis.

ii In their second paper the authors record experiments which follow up the work recorded in their first paper which showed that injection of *Ascaris* extracts into the veins of normal dogs causes a discharge of histamine into the general blood circulation. Because there is considerable decrease of the total histamine which can be extracted from pieces of liver taken after the shock produced by the *Ascaris* extracts has occurred, the authors conclude that most of the histamine discharged into the blood during the shock comes from the liver. In this second paper experiments are, however, recorded which show that the *Ascaris* extracts cannot cause a discharge of histamine from the livers of dogs previously sensitized by two subcutaneous injections of the *Ascaris* material. When these livers were perfused with Tyrode solution or defibrinated blood. Two of the dogs used for these experiments had been previously sensitized to horse serum but the perfusion of horse serum through their livers did not cause a discharge of histamine. The authors therefore concluded that direct contact of the antigen with the sensitized liver cells is not enough to cause discharge of histamine. In identical circumstances trypsin and mercury bichloride perfused through the livers regularly caused a discharge of copious amounts of histamine.

The authors also describe in this paper a mechanical type of shock observed in about 5 per cent of the dogs into which *Ascaris* extracts were injected. This form of shock is characterized by a profound fall in the blood pressure in the carotid artery but no increase of the blood histamine or heparin. Apparently it depends upon a mechanical obstruction of the hepatic blood vessels by clumped leucocytes and blood platelets without very much discharge of active substances.

Experiments are also described which indicate that the intravenous administration of liver glycogen partially or completely desensitizes the animal to the *Ascaris* extract and that the discharge of histamine and heparin from the liver cells can be entirely prevented by the administration of glycogen. The authors adduce as the explanation of this inhibition the fact that liver glycogen almost entirely removes platelets from circulating blood and causes severe leucopenia.

iii The authors of this paper follow up the conclusion of ROCHA E SILVA and GRAÇA (see ii above) that the contact of *Ascaris* antigen alone with

the cells of the liver of the dog is not enough to produce an appreciable discharge of histamine from the liver cells. They claim that they have shown that the blood contains all the constituents which are necessary to do this when *Ascaris* antigen is added to the system.

The preparation of the *Ascaris* extracts and the method of perfusing the liver were those which were described in the earlier papers except that the blood (800 cc.) used for perfusion was collected over a 3.8 per cent solution of sodium citrate (200 cc.) in a paraffined beaker. For the methods of estimating the velocity of the perfusion, the number of the blood platelets and the amounts of histamine, heparin and plasma trypsin the paper itself must be consulted.

The authors conclude from all their results that the shock produced by *Ascaris* extracts and anaphylactic shock have the same mechanism. When the isolated liver of the dog is perfused with citrated whole blood contained in paraffined receptacles a conspicuous decrease of the leucocytes and blood platelets follows the injection of *Ascaris* extracts into the cannula. Usually small amounts of histamine and of an anticoagulant (heparin) are released into the perfusing blood and in one instance considerable amounts of both were discharged from the perfused liver. This definitely shows that intact blood contains the factors which are necessary to produce a release of histamine and heparin from liver cells when the [*Ascaris*] extract is added.

Microscopical examination of smears made from pieces of liver taken before and after the shock in the intact unanaesthetized dog showed that platelets formed enormous aggregates which disappeared or partially disintegrated during the later stages of the shock. Plasma trypsin free and total, was estimated in the blood used for perfusion before and after injection of the *Ascaris* extracts. Similar estimations were made in the circulating blood of the intact dog which was given *Ascaris* extracts intravenously. Although, in a few instances there was a clear indication of the activation of plasma trypsin, usually there occurred, especially at the height of the shock, a definite decrease of free trypsin. This decrease of free trypsin was attributed to the appearance of heparin in the circulating blood. The authors discuss the probable chain of reactions which leads to the discharge of histamine and heparin from the parenchyma of the liver of the dog during anaphylactic shock and give a diagram of these. They also discuss the correlation between these reactions and the clumping and disintegration of blood elements especially the platelets which occur in the liver capillaries.

WHARTON D. R. A. & STELMA, T. Comparative Cutaneous Tests for Filariasis with Antigens of Different Dilutions. *J. Infect. Dis.* 1946 Jan.-Feb. 178
No. 1 49-59 11 refs.]

It is not possible to summarize here the interesting details contained in this paper. The publication and discussion of them are valuable because they illustrate important sources of error against which those who attempt cutaneous tests with filarial antigens have to guard. This abstract may advantageously be read together with that of WARREN *et al.* printed below.

The authors of the present paper summarize some of the relevant literature and point out that the cutaneous test for filariasis has two weaknesses—it cannot differentiate between infections with the different species of filaroid nematodes parasitic in man, and some 10 per cent. of the tests done give false

Helminthiasis

Vol 43 No 11]

positives (see however below) The antigen used was prepared from vacuum dried specimens of *Diriofilaria immitis* ground up with saline to make a dilution of 1 100 This dilution was then frozen and thawed alternately twice during one day heated for four hours at 56°C and centrifuged at 2 500 r p m. for 30 minutes The supernatant extract was then fractionally sterilized at 56°C tested for sterility phenolized to 0 3 per cent and diluted with physiological saline for use The authors think that the general opinion is that the immediate reaction is the significant one and that the index of the strength of the reaction is in the following order erythema weal a weal with pseudopodia singly or in combination but various authors have varying criteria on the flexor the positive reaction The present authors have their injections on the flexor surface of the forearm at a distance of 10 cm apart but even when this was done with the swelling and erythema of delayed reactions sometimes became confluent of 1 100 preserved with 0 3 per cent phenol and used at the same dilutions as those of the filarial antigen Delayed reactions resulted when the stronger antigens were used These could begin as early as one hour after the injection but did not develop in one case until three days after it In some cases the arm was incapacitated by the delayed reaction The delayed reaction in filariasis usually develops rapidly and is a deep extensive swollen erythematous rubbery zone which itches and feels heavy Farley identifies it with Calabar swelling Four series of subjects were used numbering 286 in all Series 1 were 29 filarous seamen from the Dutch West Indies together with 4 other members of the same ship's crew from the same endemic area These men were tested with antigen dilutions of 1 1 000 and 1 8 000 Series 2 acted as controls of the New York Hospital all of them being allergic to various substances Series 3 was composed of 153 individuals some of whom had a history of filariasis or had been exposed to infection in an endemic area and most of whom were allergic to various substances These were tested with high dilutions of 1 20 000 up to 1 800 000 a dose of 0 02 ml of the antigen being given The dog serum control fluid used to test this series was diluted to 1 100 000 and no phenol was used in any of the fluids injected Series 4 consisted of 46 men under observation for filariasis or other infections acquired in the South Pacific These were tested with dilutions of 1 1 000 to 1 100 000 of the antigen and 1 10 000 of the dog serum control fluid the doses injected being 0 02 ml

The authors claim that the results indicate that a dilution of 1 8 000 of the antigen used given in a dose of 0 01 ml is an effective antigen but that it does not as Borzevich and Hutter (this Bulletin 1944 v 41 1055) claimed screen out false positives because the present authors in the tests of Series 2 obtained with this dilution 5 6 per cent of false positives When however the 1 100 000 dilution was tested on Series 3 only 2 per cent of false positives were obtained This dilution gave on the other hand positive tests with only 80 per cent of infected persons so that it may need to be supplemented with a dilution of 1 20 000 The higher dilution is less likely to produce the objectionable delayed reaction mentioned above The results show that it is essential to use dog serum as a control The authors found no evidence of a cross reaction in persons infected with other species of parasitic animals which included malan parasites, *Erlamoeba histolytica* hookworms and *Giardia* Unlike Borzevich and Hutter the authors could not find any evidence that the filarial substance used was toxic when large amounts (250 mgm. of the residue after centrifugation of the saline extracts of worm substance and the equivalent amount of whole worm powder per animal) were injected into rabbits. The same rats (*Sigmodon hispidus littoralis*) infected with the filarial

species *Litomosoides carini* tolerated massive doses of *Dirofilaria immitis* material (up to 25 mgm. of powdered *Dirofilaria immitis* in physiological saline). When death of these rats was caused by higher doses it appeared to be due to anaphylactic shock. *G. LaPage*

WARREN Virginia G. WARREN J & HUNTER, G W. Studies on Filariasis. I. Serological Relationships between Antigenic Extracts of *Wuchereria bancrofti* and *Dirofilaria immitis*. *Amer J Hyg* 1946 Mar \ 43 No 2, 164-70 1 fig 12 refs

The authors set out to seek for the diagnosis of filariasis a better test than biopsy or the discovery of microfilariae in the blood. They summarize the contents of several papers, all of which have been abstracted in previous issues of this *Bulletin* which record results obtained with antigens obtained from the filaroid species *Dirofilaria immitis*, *Litomosoides carini* and *Confortaspiculis ricas*. The authors say that it is generally agreed that extracts of these species will give cutaneous reactions in persons infected with *Wuchereria bancrofti* and that precipitin and complement fixation tests done with them are also successful to a certain degree. Antigens have also been made from *Wuchereria bancrofti* see ACTON and RAO this *Bulletin* 1933 v 30 699] and OLIVER-GONZÁLEZ and BERLOVITZ [this *Bulletin* 1945 v 42 219], but these gave disappointing results.

The present authors made antigens from the microfilariae of *W. bancrofti* and also from adult *D. immitis*. They describe in detail the methods used for making them. Microfilariae of *W. bancrofti* were isolated from human blood by centrifugation, frozen, dried *in vacuo*, powdered, dried again over CaCl_2 and a 1 per cent suspension was then made in physiological saline. This was refrigerated at 5°C. for 24 hours and then alternately frozen and thawed several times and put in a water bath at 56°C. for 4 hours and often shaken to decrease any anticomplementary properties. It was then centrifuged at 500 r.p.m. for 10 minutes. The process was sterile throughout. The resulting supernatant fluid was used as the antigen being preserved by the addition of 0.3 per cent phenol. The sediment was used for the immunization of rabbits. The control used was a leucocyte-stroma antigen made in the same way from normal human blood known to be free from microfilarial larvae. The *Dirofilaria immitis* antigen was made from dried adult specimens obtained from the heart and lungs of dogs. With these antigens the authors did complement-fixation tests, intradermal tests and studies of cross antigenicity. For the details of the technique of these experiments the paper itself must be consulted.

Complement fixation tests were done upon the sera of 12 subjects who had been clinically diagnosed as suffering from filariasis. Antigen dilutions of 1/100 and 1/800 were used with serum dilutions of 1/1 and 1/128. All the sera gave negative results with the *W. bancrofti* antigen even though motile microfilarial larvae were present in two of these sera. All the sera on the other hand, gave strongly positive fixation with the *D. immitis* antigen. The former antigen thus appears to be unsuitable for complement fixation tests. The authors thought that the failure of the *W. bancrofti* antigen might have been due to the use of an antigen deficient in a water soluble component lost in the washings of the citrated blood used but all attempts to make an antigen containing this water-soluble component or to make a polysaccharide antigen failed to produce an antigen which would give positive results.

Intradermal tests were done on 32 soldiers who had recently returned from a hyperendemic area in the Southwest Pacific. They showed good clinical evidence that they were suffering from filariasis. The sera of 30 of these men gave positive fixation with *D. immitis* antigen, but microfilarial larvae

Helminthiasis

Vol 43 No 11]

were not found in the blood. Each man was given an injection of 0.025 ml of dilutions of 1 4 000 1 8 000 and 1 12 000 of the *W bancrofti* antigen and dilutions of 1 8 000 of the *D immitis* antigen. Control tests were done with 1 4 000 dilutions of the leucocytestroma antigen and with 1 8 000 dilutions of dog serum in physiological saline to which 0.3 per cent phenol had been added. The criterion of a positive reaction was a weal which had at the end of 10 minutes a diameter at least 3 mm greater than that of the control.

Of the 32 subjects 22 gave positive reactions to the *W bancrofti* antigen 23 were positive to the *D immitis* antigen 17 were positive to both and 4 to neither. Two subjects whose sera gave no complement fixation to *W bancrofti* antigen and yet contained microfilarial larvae gave positive intradermal reaction to *W bancrofti* antigen and strongly positive ones to *D immitis* antigen.

When 75 control subjects with a history of allergy were tested none of whom had been in an endemic area only four of them gave a cutaneous response to *W bancrofti* antigen. When 21 others infected with intestinal nematodes the species of which are not given were tested none gave a positive intradermal reaction with *W bancrofti* antigen.

In order to explain the discrepant results obtained with these two antigens the authors tried to prepare specific antisera. Four rabbits were immunized with 1 100 dilutions of both antigens and with sediments of worm material obtained from the centrifugation during the preparation of the antigens. Two rabbits were given the *W bancrofti* sediment and two were given the *D immitis* sediment all having 10 injections intraperitoneally. The sera of these rabbits were then titrated against the antigens and against the human leucocytestroma antigen for complement fixation. With both antigens a high titre occurred but the antisera also reacted to an equal degree with the leucocytestroma antigen. No fixation occurred however when normal rabbit sera were used.

To study cross-antigenicity one portion of a high titre *W bancrofti* serum was absorbed for 18 hours at 5°C with an excess of *D immitis* antigen and a second portion with an excess of *D immitis* antigen and a third with the leucocyte-stroma antigen. Similar absorptions of a high titre *D immitis* antigen were done but none were done with the leucocyte-stroma antigen. It was found that absorption of antisera with the homologous antigen removes all activity from the immune sera but that absorption with the heterologous antigen removes only the heterologous antibody. The authors concluded that both the filarial species used contain a species specific and also a group-specific antigen.

SUTLIFF W D & ANTONIO ECHANDI G R. Pinworm (*E. vermicularis*) and other Intestinal Parasites in Costa Rican Children. *J Parasitology* 1946 June v 32 No 3 233-6 [11 refs.]

DORIN R P. The Preparation and Demonstration of an Antiserum for *Trichinella spiralis*. *J Parasitology* 1946 Feb v 32 No 1 83-8.

The author describes the fixation of *Trichinella spiralis* antigen on to aluminum cream preparations by the method originally described by HERTSCH and WELKER (*J Infect Dis* 1933 v 53 309) and used successfully in the field of organ sera by SPINKA and WEIGSELBAUM (*Proc. Soc. Exper Biol. & Med* 1938 v 38 447) MANN and WELKER (*Amer J Cancer* 1940 v 39 360) and COHEN and FREDA (*Proc Soc Exper Biol & Med* 1940 v 43 22). The author claims that the method makes possible a single injection of

the antigen and the use of material which need not be sterile and that the rabbit into which it is injected produces antibodies for a long while.

The author used larvae of *Trichinella spiralis* isolated from rat muscle by digestion, and washed in physiological saline until the Burret test was negative. If, he says this washing is not done the experimental animal dies possibly from peptone shock. The larval material was then absorbed on to aluminum cream by the method of WELKER and TRACY (*J. Biol. Chem.* 1915 v. 22, 55). The material thus obtained was then injected into rabbits by the method of Hektoen and Welker. Variations in the method of making the antigen resulted in the production of different titres in the antisera obtained, and these are discussed by the author. The antigen used to find the titre of the antisera was a commercial preparation made by the Eli Lilly Co. and used for intradermal tests in the diagnosis of trichiniasis. This antigen was adjusted to neutrality with acetic acid and its nitrogen content was determined by the Koch-McMeekin micro-Kjeldahl method. The author found that this antigen did not give a positive reaction with an antiserum made from rat tissue by the method of Spinka and Weichselbaum. None of the rat tissue antisera reacted positively with rat tissue autolysates made by the method of Mann and Welker. The antisera were usually made by the method of Spinka and Weichselbaum. It was found that the injection of a suspension of 400 000 *Trichinella* larvae in 80 cc. of saline with the addition of 120 cc. of aluminum cream gave after centrifugation the desired amount of material for injection into each rabbit. Each rabbit thus received 400 000 *Trichinella* larvae.

Injection of these antigens gave antisera with titres of 1 4 000 1 5 000 1 6 000 and 1 11 000. When rabbits were given by the mouth doses of larvae near the lethal dose antisera were obtained with titres ranging up to 1 8 000 according to the length of time since the injection.

The effect of the injection of these antigens upon the resistance of rabbits to infection with *Trichinella spiralis* was striking. Three rabbits were injected with antigen fixed on aluminum cream, and these were used as actively immunized animals. These and also five normal rabbits as controls were each given by the mouth 20 000 *Trichinella* larvae in 10 cc. of saline. Two of the controls died and one of the immunized rabbits died on the 32nd day from the effects of a bite by one of its mates. The others were killed on the 43rd day after the doses of larvae and equal weights of their muscles (tongue masseters diaphragms and muscles of the two forelegs) were digested. In one immunized rabbit the only larvae found were the ten in the muscles of one of the forelegs the titre of the antiserum of this rabbit was 1 6,000. In the other immunized rabbit 90 larvae were found in the tongue 120 in the masseters, 150 in the diaphragm 200 in the muscles of one foreleg and 800 in those of the other the titre of the antiserum of this rabbit was 1 5 000. In the controls from 7,800 to 12 000 larvae were found in the tongue from 16,900 to 23 700 in the masseters from 18 400 to 32,700 in the diaphragms, from 30,500 to 45 000 in the muscles of one of the forelegs and from 30 700 to 47,500 in those of the other. The conclusion was drawn that the actively immunized rabbits had resisted the infection.

It was found that injection of the immune sera also protected the rabbits. Six rabbits were given a sublethal dose of 4,500 *Trichinella* larvae. Three of them were then given 9 cc. of immune serum intraperitoneally in doses of 3 cc. each, one on the day before the larvae were given one on the day on which they were given and one on the day after they were given. The three other rabbits were given normal rabbit serum in the same way. Two uninfected rabbits were given the same amount of normal serum as an additional control. Eleven days later it was found that (a) the rabbits given larvae and immune serum were sleek active responsive and clean-looking and apparently normal

Deficiency Diseases.

Vol 43 No 11]

(b) the rabbits given larvae and normal serum had bloody red noses and ruffled fur and were unresponsive and apparently moribund. (c) the controls given normal serum only were normal. The conclusion was drawn that the immune serum had protected the rabbits. The author claims that the anti sera are specific to larvae of *Trichinella spiralis* but not for any of the other proteins. G Lafage

LEON L. A. Cuarto caso de infección humana por *Agamomermis*. [Fourth Case of Human Infection with *Agamomermis*] *Rev Med Trop y Parasit Habana* 1946 Jan-Mar v 12 No 1 25-6 3 figs

This paper describes a nematode found in the excreta of a mestizo child aged five who came for treatment for infection with *Ascaris lumbricoides*. The nematode is briefly described and the author regards it as a species of *Agamomermis* a name given to immature forms of species belonging to the nematode family Mermithidae which have been found in the past three times in human beings and are noted in text books of parasitology. All are regarded as accidental parasites and the specimen here described is regarded by the author as an accidental parasite ingested with the food, possibly with raw fruit. [The Mermithidae are nematodes whose larval phases are parasitic in earwigs, grasshoppers and some other insects the adult phases being non-parasitic and living in the soil. *Agamomermis* should not be confused with *Agamermis* which is the name of a true genus of the family Mermithidae.] G Lafage.

DEFICIENCY DISEASES

CLARKE C A & SNEDDON I B Nutritional Neuropathy in Prisoners-of-War and Internees from Hong Kong. *Lancet* 1946 May 18 734-7 [Summary appears also in *Bulletin of Hygiene*]

This report deals with the condition after their arrival in Australia of 200 patients who had been prisoners in Hong Kong from late 1941 until September 1945. On admission to hospital none of the patients showed any of the classical signs of vitamin deficiency but 74 of them showed grossly abnormal neurological signs which were classified as optic atrophy and ataxic paraplegia in 31 patients, ataxic paraplegia alone in 21, optic atrophy alone in 13, optic atrophy, nerve deafness and ataxic paraplegia in 6, and optic atrophy and nerve deafness in 3.

The commonest neurological abnormality was impairment of visual acuity (53 cases) due to central and paracentral scotomata. The ocular fundi showed partial optic atrophy and in many cases macular degeneration was present. The parasthesiae were like those of polyneuritis but tenderness of the calves was not found. Some cases showed increased deep reflexes, spasticity and ataxia out of proportion to the degree of anaesthesia and the condition of some suggested amyotrophic lateral sclerosis. No significant changes were found in the blood nor was there any evident relationship between neurological disturbance and achlorhydria. No general lowering of the level of the plasma proteins was found and oedema was never a prominent feature. Treatment for two months with a high-calorie diet and massive doses of vitamins led to subjective improvements in many cases but the neurological signs remained unchanged. The authors believe that the neuropathy they describe results from a toxic or antivitamin principle in the diet rather than from a plain dietary deficiency. H E Harding

Scattered inflammatory cells as well as occasional small foci are still present in the upper layers of the corium. Some restitution has occurred in the basal layer and some of the rete pegs are of usual width and appearance. Others however show persistent degenerative changes in the basal layer with consequent sharpening of their outlines. Small masses of pigment are occasionally seen in the papillary and subpapillary connective tissue. When seen in this stage it is extremely difficult to differentiate this condition from other toxic dermatoses in tissue sections.

Certain histological changes are common to the three stages—these include thickening of the horny layer, blocking of the follicular orifices by keratin plugs and degenerative and liquefactive changes in the cells of the basal layer of the epidermis. Spongiosis often occurs. Usually there is an increase of pigment in the basal layer. A cellular infiltrate which varies with the severity of the disease and which chiefly consists of lymphocytes and histiocytes is present in the papillary and subpapillary layers of the corium, and tends to cluster round hair shafts, hair follicles and glandular tissues. Also aggregations of pigment can be noted—particularly in acute cases—in the two upper layers of the corium and most characteristically at the tips of the papillae. The pigment is a melanin and most of it is enclosed in macrophages although some may be scattered in the stroma.

Rosenthal gives full reports concerning blood examinations which were made in 18 cases. A moderate anaemia was found in 12 of these but in one case the red cell count was as low as 980 000 and the haemoglobin 20 per cent. Lymphocytosis and slight degrees of eosinophilia occurred in some 70 per cent. of the cases. Occasionally biochemical changes were noted in the blood—these consisted in a decrease of the total protein and a lowering of the albumin-globulin ratio but the author carefully states that as biochemical examinations were made only in the more severe cases the figures which he gives are not representative for the whole series. In a complete statistical study of unselected cases the figures would undoubtedly be different. Two patients had severe haemopoietic disturbance and one of these died. A blood culture after death revealed the presence of haemolytic staphylococci and streptococci. A full account of the post mortem findings is given and the full diagnoses are summarized thus—

(1) Lichen planus (New Guinea) (2) aplastic anaemia (3) focal myocardial hemorrhages and necrosis (4) bilateral pleural effusion (5) pulmonary edema (6) congestion of spleen (7) hepatitis subacute (8) bilateral pelvic hemorrhages in kidneys (9) subarachnoid and intraventricular hemorrhages (10) hypoplasia and fatty change of bone marrow (11) multiple ecchymoses of skin, voluntary muscles, diaphragm and viscera.

The lesions found in the liver were regarded as being of special interest—they consisted in subacute hepatitis characterized by degeneration of liver tissue and accumulation of chronic inflammatory cells. "In addition isolated masses of pigment were found which were iron-negative and melanin positive (Becker stain). The Kupffer cells also contained large amounts of pigment. It is assumed that this pigment is bile pigment. However there is some resemblance to the melanin pigment of the skin.

With ultraviolet light the liver showed a marked greenish fluorescence. The presence of this marked fluorescence in a pathologic liver of a patient who had not had atabrine (mepacrine) for 6 weeks prior to his death again called attention to the possibility of atabrine being a factor in this disease. Since however this is the only case that I have seen, no definite conclusions are warranted.

The author concludes by stating: "It still is not clear why this condition should occur proportionately much more frequently in New Guinea than other

regions where similar conditions prevail. It is possible that atabrine is only one of the factors in a chain of causes which may eventually be found in diet, climate, ingested drugs insecticides or infection with malaria.

ERRECART L M Sobre veinticinco casos de esporotricosis en el Departamento de Flores. [Twenty-Five Cases of Sporotrichosis in Flores.] *Arch Uruguayos de Med., Cirug y Especialidades* 1946 Mar v 28 No 3 249-53 English summary

The author diagnosed twenty-seven cases of sporotrichosis during fourteen years. He thinks that sporotrichosis is a frequent disease not only in Flores but also in the other localities of Uruguay. No one lesion of the lungs was observed. Twenty six cases were localized in the upper limbs and one in a leg. All patients were males.

HEAT STROKE AND ALLIED CONDITIONS

MACKWORTH N H Effects of Heat on Wireless Telegraphy Operators Hearing and Recording Morse Messages. *Brit J Indust. Med* 1946 July v 3 No 3 143-58 9 figs [Summary appears also in *Bulletin of Hygiene*]

The decline in the capacity for manual work caused by exposure to high air temperatures especially in humid atmospheres has long been recognized. It is a matter of common experience that one's inclination for mental effort may diminish in very hot environments but the effects of heat on the capacity for mental work have not hitherto been clearly demonstrated experimentally. That is probably due to the experimental arrangements employed in some of the earlier investigations for in those studies different types of tests were used during any particular work-spell so that at intervals of 20 or 30 minutes there was a change of activity which introduced the powerful stimulus of variety. Many tasks are monotonous rather than variable and to assess the influence of temperature on the performance of such tasks protracted experiments are necessary. Such experiments were performed in the research described in this important paper with the result that a diminished performance in very hot environments was clearly shown.

The research was carried out on behalf of the Medical Research Council's Royal Naval Personnel Research Committee. That Committee wanted to know whether high temperatures affected some forms of human activity more than others so that it could be ascertained whether certain compartments in H.M. ships should have priority in the allocation of air-conditioning equipment and further it was desired to learn the extent of the overlap between the physiological effects of heat and the effects of heat on human performance as measured by psychological experiment.

In the study here reported the performance of eleven physically fit wireless telegraphy operators was examined. Before the main tests they were acclimatized by exposure to effective temperatures of 87.5°F to 97°F for three hours a day five or six days a week over a period of seven to eleven weeks. On the test days work was done for three hours during which period nine messages each of 250 groups, were transmitted at a speed of 22 words per minute. That is to say messages were transmitted for about 16 minutes with 3-minute intervals between messages.

The wind velocity was 100 ft. per min. throughout the series of tests, the dry-bulb temperature on different days was 85° 90° 95° 100° or 105°F., and in each instance the wet-bulb was 10°F. below the dry-bulb temperature. These conditions represented effective temperatures of 79° 83° 87.5° 92° and 97°F. Rectal temperatures were measured at the beginning and end of each work-spell. The men wore gym-shoes and white drill shorts and wrote the morse messages while seated at a table. There was plenty of unsalted water for drinking and each had a daily ration of 10 gm. of salt in addition to the ordinary dietary intake. During the run of the experiments the men had no exact knowledge of the accuracy of their performance on a particular day.

The main conclusions drawn from this investigation are —

1 Hot and moist atmospheres seriously impaired the accuracy with which these trained men could record morse messages heard over their headphones.

2 A statistically significant reduction in their accuracy first appeared when they were exposed to an effective temperature of 87.5°F. (with 85°F. dry bulb and 83° wet-bulb temperature). It had earlier been observed that most wireless telegraphy ratings in the Eastern Fleet had to work at effective temperatures of more than 84°F. and that conditions were worse during prolonged spells at action stations.

3 Hot and moist atmospheres raised the rectal temperatures.

4 Rectal temperature did not give even an approximate idea of the accuracy of work at wireless telegraphy reception.

5 Hence raised body temperature did not cause deterioration in ability to receive wireless signals, within the range of atmospheric conditions encountered by ratings in the Eastern Fleet.

It was noteworthy that the exceptionally competent members of the group were less affected by the difficult atmospheric conditions than men regarded as very good operators. Men of ordinary ability showed the greatest deterioration of all. [This is an interesting point. Other studies of industrial fatigue have shown that the more competent workers show less sign of fatigue than their fellows.]

There were no signs of cumulative effects from day to day but during a 3-hour spell the number of errors per hour rose progressively. Commonly errors were twice as numerous in the second hour as in the first and three or four times as numerous in the third hour. Severe head colds increased the rate of this falling-off in accuracy.

Thomas Bedford

MISCELLANEOUS DISEASES

MANSON BAHK P. Some Tropical Diseases in General Practice. "A Post War Legacy" *Glasgow Med J* 1946 May v 27 No. 5 123-30

In this lecture Sir Philip Manson-Bahr reviews briefly the experience of certain tropical diseases as they affected the troops in the recent war and its predecessor and as they may affect practitioners in Britain who are faced with the difficult questions of diagnosis and treatment of these cases of, to them, uncommon and baffling complaints. He brings the experience of a lifetime to the evaluation of the important features noting that problems now sometimes regarded as new are, in fact, repetitions of those which arose 30 years ago. The sequelae of amoebiasis for instance, are rightly regarded seriously but after the war of 1914-18 it was found that the disease gradually petered out and no doubt this will happen again in the meantime effective treatment is by no means impossible and it is important to avoid the amoebiasis neurosis

Malaria has been controlled during the war more effectively than ever before and treatment is now very good. Although it is a correct attitude of mind to think first of malaria in soldiers who return from the East, a too facile diagnosis of enlarged spleen as due to malaria may lead to serious errors. The enlarged spleen usually retracts and disappears after one year's residence in a temperate climate, and in such patients some other cause should first be sought.

Sprue is still a mystery. The author favours the view that it is due to some infective agent. In treatment careful dieting and nursing are needed, but injections of crude liver extract are very useful. *Charles Wilcocks*

McCoy O R. Precautions by the Army to prevent the Introduction of Tropical Diseases. *Amer J Trop Med* 1946 May, 26 No 3 351-5

In this address to the Annual Meeting of the American Society of Tropical Medicine in November 1945 Colonel McCoy considers the problems arising from the return of troops from tropical theatres of operation to the United States.

He begins by pointing out that high standards of preventive medicine have been enforced among troops overseas and that troops in endemic areas have been immunized against such infections as yellow fever, cholera and plague.

Malaria has been the greatest disease problem and the author reveals that between December 1941 and June 1945 there were 430 000 hospital admissions for malaria in the U.S. Army.

Steps taken to minimize the hazards of malaria recurring when soldiers return to the United States include a co-ordinated mosquito control organization, continued suppressive medication for 28 days after arrival in the United States, and examination of the man and his blood before demobilization if conditions indicate it.

Colonel McCoy goes on to discuss the problems of dysentery, dengue, sand fly fever and scrub typhus. The hazard from dengue is the greatest and stringent *Aedes* control is essential at Army bases and airports. The possibility of the introduction of *Ancylostoma duodenale* is discussed. This species presents a greater problem than *Necator americanus* because it is more harmful, more resistant to climatic conditions and less amenable to treatment. Other helminthic diseases are also mentioned. General quarantine measures have been improved and strengthened, and a joint Army, Navy and Public Health Service Quarantine Board has been set up, and this Board takes advantage of the facilities for immunization and supervision exercised over members of the Forces.

The problems and the measures designed to deal with them are on orthodox lines, and the paper contains little that is original for the British reader. The relative urgency of the problem is underlined by two local factors: firstly, that American citizens have been spread over a larger area of the tropics and exposed to greater hazards of disease which is indigenous there than ever before in their history; secondly, that conditions in certain parts of their vast Continent are favourable to the maintenance and dissemination of some tropical diseases which would not flourish in more evenly temperate climates. The urgency is therefore more obtrusive to United States health legislators than to our own.

H J O'D Burke-Gaffney

TRENCHARD H J. Inability to work in a Tropical Climate. *Brit. Med. J* 1946 Sept. 21 416-18.

This paper discusses the factors in invaliding between October 1944 and September 1945. 373 Royal Air Force men, chiefly ground staff, found unfit for

duty in South East Asia although not necessarily unfit for further military service in the United Kingdom.

The age of the men varied from 18 to 47 the majority being between 20 and 30. Most had been in the R A F between two and five years and their service overseas varied from 2 to 51 months the incidence of invaliding excluding that due to tropical diseases showed peaks during the first twelve months and after eighteen months of service overseas.

The principal causes of invaliding were—injuries 50 organic diseases excluding pulmonary tuberculosis which was not dealt with at this centre 178 and psychological abnormalities 147. The majority of the invalided were fit enough to travel by normal troop arrangements only 60 of whom 18 had injuries requiring transport by hospital ship.

Of the surgical cases the injuries formed an important proportion although only five were directly due to enemy action while of the surgical diseases disorders of the urinary system particularly calculus were noteworthy.

There were 50 patients with skin diseases of whom 10 had trouble before going overseas and the commonest conditions were epidermophytosis 12, and seborrhoeic dermatitis 12.

Tropical diseases accounted for 59 invalidings of which 34 were due to sprue and 15 to amoebiasis only 2 patients were invalided with malaria a low figure thought to be due to the efficiency of mepacrine suppression. The main causes for repatriation in amoebiasis were amoebic hepatitis persistent relapses of bowel infection and the development of a pre-sprue type of condition.

Of psychological abnormalities anxiety state was diagnosed in 86 patients hysteria in 33 psychoses mostly schizophrenia in 15 and psychopathic personality in 11. The principal precipitating factors of the anxiety neuroses appeared to be family or financial worries infidelity of the wife or discomforts of overseas service but in 15 cases no outstanding factor could be discovered. In those suffering from hysteria the precipitating cause appeared to be a subconscious desire to return home while the principal symptoms were headaches depression dizziness or dyspepsia. A feature of the psychotic patients and those diagnosed as being of psychopathic personality was the length of time that they were able to serve overseas before requiring invaliding some carrying on for more than two years.

HEUNG R. Some Advances in Medical Treatment. *J Indian Med Ass.* 1948 June 15 No 9 308-12 '39 refs

This is a succinct but useful review in which modern work on the sulphonamides penicillin streptomycin prostigmine nicotine acid pyridoxine thioracil and the anti-malarial drugs is summarized. Sulphadiazine has almost supplanted the other compounds of the series and the author noting its efficacy in bacillary dysentery remarks that there is no reason why it should not be equally effective in cholera. He gives concise information on the use of penicillin in gonorrhoea according to the most recent work available. The story of the Australian work on mepacrine and Paludrine is briefly recounted.

Charles Walcock

FEIGENBAUM, A & KORNBLUTH W. Behcet's Disease as Manifestation of a Chronic Septic Condition connected with a Constitutional Disorder. With a Report of Four Cases. *Acta Med Orientalis (Palestine & Near East Med J)* 1948 May 5 No 5 139-51 [Numerous refs.]

The authors present a very clear account of this peculiar disease which is characterized by ulcers in the mouth and on the genitalia with eye lesions—

hypopyon irido-cyclitis retinitis optic neuritis—and by an eruption like that of erythema nodosum. Though cases have been reported from time to time since the end of the last century little if anything is known concerning the aetiology or pathogeny and treatment is far from satisfactory. Sometimes one or more of the symptoms mentioned above is absent. Partial cure seems to occur spontaneously in some cases but relapses come on after intervals of varying length perhaps 6-7 years.

Four cases are detailed in this paper three males of 24 25 and 28 years and one female of 25 years. One man died with nervous symptoms headache dizziness and convulsions the woman left hospital and could not be traced two improved. *Staphylococcus aureus* was cultivated from the lesions and the syndrome is thought to be due to a chronic septic condition in persons pre disposed by in most cases latent tuberculosis trauma playing a part and possibly a large part in the primary localization of lesions. Though improvement in the general health takes place in non fatal cases it will be obvious from the severity of the eye symptoms that the damage to the sight may be great and permanent. Treatment by sulphonamides and penicillin and by injection of autogenous vaccines has been tried in some with apparent benefit but it is thought that the dosage may have been inadequate. The authors have given a helpful review of the literature of the subject and a very full list (two complete pages) of references to this interesting condition. [See also this *Bulletin* 1944 v 41 780 1946 v 43 157] *H Harold Scott*

RAO V G Some Observations on Cases of Ascites in Hyderabad-Deccan.
J Indian Med Ass 1946 May & June v 15 Nos. 8 & 9 254-62 295-300 [59 refs.]

Among 343 consecutive cases of ascites admitted to the Osmania Hospital in two years there were 52 in which no definite organic disease was detected these are classed as being due to nutritional deficiency. Most of the 52 were young or middle-aged adults of the labouring class whose diet provides sufficient calories but is of poor quality and deficient in protein. Although there were approximately equal numbers of the two sexes in the general admissions to hospital 46 of these 52 cases of nutritional ascites occurred in males. In some patients the ascites was accompanied by pleural and pericardial effusions and by anaemia of moderate degree. Serum proteins were determined in 8 patients in 7 of whom the ratio of globulin to albumin was greater than 1.

The majority of the patients recovered with rest in hospital and on a diet more liberal and better balanced than that at home. Complete disappearance of the ascites followed by gain in real weight was obtained in 32 cases and the condition of 10 others was improved. Seven patients died.

Only a few patients were followed up after leaving hospital. 15 were known to be in good health for periods varying up to 2 years. Four patients who were classed as having 'nutritional ascites' and who were discharged after clinical recovery returned later two with cirrhosis of the liver one with pulmonary tuberculosis and one with pleurisy.

The second part of this paper records the findings in the 108 cases of portal cirrhosis included in the 343 cases of ascites. The condition appears to be common in India but apart from a suggestion that defective diets play some part there is no evidence to explain its etiology. Twenty of the 108 patients were vegetarians and total abstainers because of their religion and from only 40 of the remainder could a history of occasional 'toddy' or 'sundhi' drinking be obtained. (The alcoholic content of these drinks is only about 7 per cent.)

Bleeding was uncommon in these patients—only one had haematemesis three had melæna, and five had bleeding piles. Examination of a few cases showed moderate anaemia, and low serum proteins with a reversed albumin/globulin ratio. Response to treatment was unsatisfactory and unlike the patients with nutritional ascites many of the patients died in hospital while most of the remainder showed little improvement after repeated paracenteses.

It is suggested that cases classed as nutritional ascites may at first be due to simple malnutrition without gross hepatic lesions and may be capable of recovery but that a continued state of malnutrition may ultimately result in a fully developed picture of portal cirrhosis.

BECKER B. J. P. Cardio-Vascular Disease in the Bantu and Coloured Races of South Africa. I. Incidence, Pathology and General Features. *South African J Med Sci* 1946 Apr v 11 No 1 1-14 3 figs [13 refs.] II. Congenital Heart Disease *Ibid* 15-17 [10 refs.] III. Rheumatic Heart Disease. *Ibid* 18-34 1 fig [43 refs.]

These three papers, or sections of one contribution, are excerpts from a doctorate thesis. They comprise an analysis of those among 3,000 autopsies performed at the Johannesburg General Hospital during 14½ years ending June 1938 showing cardiac or cardio-vascular disease. Some 12 per cent. of Bantus and coloured persons were found to have died from circulatory disease a proportion about the same as that recorded in other parts of the world.

For the purpose of his analysis the author uses the following classification: Congenital and Acquired, 2.5 and 97.5 per cent. respectively and the latter he subdivides into three main groups: Inflammatory which includes rheumatic, syphilitic and tuberculous; Metabolic and Physical which includes atheroma, arteriosclerosis and beriberi; and, thirdly Neoplastic—a classification not altogether satisfying.

Among the 3,000 there were 1,335 or 46 per cent. showing some disease of the circulatory system. As regards sex, 1,041 occurred among 2,190 males autopsied (47.5 per cent.) and 344 among 810 females (42.5 per cent.) so that sex differences are negligible. No indication was found of any special racial susceptibility among the seven races making up the total.

Atheroma was the commonest lesion found and next to this, hypertensive heart disease but in the majority these were not the sole lesions. Tuberculous disease of the heart was found in 4 per cent. of those dying under 30 years of age and in 8 per cent. of those over 30 years; syphilitic disease was less in evidence in only 2 per cent. below 30 years and in 6 per cent. of those over 30 years.

As regards valvular lesions, there were 108 cases of aortic incompetence among the 3,000 autopsies (3.5 per cent.) 57 (1.8) of mitral stenosis, 16 (0.5) of aortic stenosis, and 5 (0.2) of mitral incompetence. There were 51 cases of aneurysm, most due to syphilitic aortitis and 37 of the patients died from rupture of them.

In the second paper the author records that there were 35 cases of congenital heart disease among the 3,000 (1.18 per cent.) excluding abnormalities of the vessels, hypoplasia and aneurysm, and displacement due to primary diaphragmatic deficiency; this figure is reduced to 13 (0.4 per cent.) Infective endocarditis was found in two only of these congenital cases.

In the third paper rheumatic heart disease is discussed in more detail. One hundred and six such (3.5 per cent.) were found among the 3,000. It was most common in the 11-20-year group constituting 10 per cent. of the autopsies and 33.7 per cent. of the cardiac cases. Among females with organic heart disease "rheumatic heart" was present in 15 per cent. among males 5 per cent. but the variation in females is stated to be 5.5-24.5 per cent. and in

males 15-85 There is thus says the author no significant difference [a conclusion not easy to follow] For this analysis the author classifies rheumatic heart disease into three main groups Acute rheumatic carditis latent (developing) carditis and developed lesions. These are each of them further sub-divided and discussed Space forbids more detailed account here those interested should consult the original paper or better still the complete thesis if it is published Suffice it here to say that the mitral valve was involved alone in 38 and together with other lesions in 42 or 80 in all The aortic valve alone was involved in 23 In about one-third of the cases of rheumatic heart disease bacterial endocarditis was superimposed the aortic valve was affected in this way more often than the mitral and both together in four Among the author's conclusions two are particularly striking First In its age and sex incidence among Bantu and Coloured races it [rheumatic heart disease] cannot be said to differ in any essential way from the condition as seen in other parts of the world secondly There is a somewhat higher incidence of bacterial endocarditis in Bantu and Coloured subjects in association with rheumatic valvulitis than occurs in other parts of the world [The whole is an interesting and painstaking study]

GENERAL ENTOMOLOGY

TRHINAEV P P [Flying Activity and Attack on Man of Various Species of *Anopheles* and *Culex* under Natural Conditions in Uzbekistan.] *Med Parasit & Parasitic Dis* Moscow 1945 v 14 No 5 15-35 11 figs. [In Russian.]

The author records the results of observations upon the flying activity and attacks upon man of mosquitoes carried out chiefly among the rice fields of Uzbekistan from March to October of the years 1939-1943 The study was restricted to *Anopheles* and *Culex* (*Anopheles maculipennis sacharovi*, *A. hyrcanus*, *A. claviger* (*bifurcatus*), *A. superpictus*, *A. pulcherrimus*, *Uranotaenia theobaldi*, *longiareolata*, *T. annulata*, *Mansonia*, *Aedes caspius*, *Aedes detritus*, *Aedes pulcherrimus*, *Aedes vexans*, *Culex*)

Counts were made by using a trap constructed as follows a sheet was suspended on four poles, with the edges touching the ground one side of the sheet being raised during the observations to form an inlet for the mosquitoes. One or two men who served to attract the insects and remained under cover of

this tent with a lamp burning all night made observations on and collected the mosquitoes, keeping hourly records of temperature, humidity and wind. When flight ceased the sheet was removed.

The results shown in numerous tables and charts were as follows: among the Anopheline and Culicine mosquitoes entering the tent unfed females formed 87 per cent. those with blood in the stomach 8.4 per cent. those with developed ovaries 2.3 per cent. males were 1.7 per cent. The maximum number of attacking mosquitoes was observed in July constituting 38.2 per cent of a total number of actively attacking mosquitoes during the whole season. The minimum density was in April (1.5 per cent.) in May (2.6 per cent.) and in October (3.1 per cent.). The temperature limit at which activity was highest was 33.5°C while at 9°C it was lowest the temperatures being between 15° and 25°C in May and 11–15 in October with intermediate values in September and April. As regards humidity it was found that 100 per cent. relative humidity had a depressing effect upon the activity of mosquitoes. The insects manifested a positive phototaxis to the weak source of artificial illumination while sunlight at temperatures not exceeding 20°C had no inhibiting effect. However high temperatures combined with intensive insolation and evaporation were unfavourable the mosquitoes keeping to their day shelters under these conditions. The mechanical and denocating action of wind proved to be of primary importance. The maximum speed of wind at which flight of mosquitoes took place was 4.17 metres per second when the speed does not exceed 2 m/sec they fly in the open air above this speed they fly low in the grass. The daily rhythm in the attacks of mosquitoes corresponds to periods of evening and morning maxima, and night and afternoon minima of flying activity. During the maximum evening periods the first mosquitoes to attack are *Aedes caspius* and *Culex* the density of which increases progressively from sunset to night after which it declines while the density of *Anopheles* begins to rise.

MARA L. Considerazioni sul rinvenimento dell' *Aedes aegypti* L. (*Dip. aedinas*) ad altitudini eccezionali e brevi note sulla fauna culicidica del M. Bizen (Eritrea, A. O.) [A Note on the Finding of *Aedes aegypti* at an exceptional Altitude with a Short Note on the Culicid Fauna of Mt. Bizen.] *Boll. Soc. Ital. di Med. e Ig. Trop.* (Sex. Eritrea) 1945 v 5 No. 5/6 189–98. [18 refs.] English summary

In this note it is said that *Aedes aegypti* L. has been found on the Bizen mountain (Eritrea, East Africa) at the exceptional altitude of 2 400 metres above sea level. This altitude is 450 metres higher than that previously quoted by other authors in Kenya Colony (1 950 metres above sea level).

WISSEUP C. B. BROTHERS W. C. EIDZ P. M. & DEONIER, C. C. DDT Emulsion applied to Rice-Field Water to control Mosquitoes. *J. Econom. Entom.* 1946 Feb. v 39 No 1 52–5

The authors' object was to run DDT emulsion into irrigation water in the channel before it flowed on to the rice field thus attaining distribution through the mechanical flow of the water. The stock concentrate consisted of 20 per cent of DDT 20 per cent. of *Trilon X 100* a proprietary emulsifier and 60 per cent of xylene this was diluted with water before application by means of a drip can.

Concentrations of DDT of less than 0.1 part per million gave very limited control. Doses of 0.2 p.p.m. and 0.4 p.p.m. gave control of breeding in fields near to the channels on which the treatment was applied, but not in the more

distant fields. A dose of 0.6 p.p.m. gave complete initial control and residual control was noted in some cases. It is concluded that the degree of control depended on (a) the concentration of the DDT emulsion in the water (b) the dosage of DDT per acre (c) the distance that the emulsion was carried in the channel before it entered the field and (d) the size of the field. Subsequent laboratory tests have shown that intense aeration of water containing DDT causes a decided loss of toxicity to mosquito larvae.

There was no noticeable damage to the rice and no decrease of plump grains in the treated fields. The mosquitoes concerned were *Anopheles* and *Psorophora*.

JAYEWICKREME S. H. & NILES W. J. Successful Feeding Experiments with an Adult Trombiculid Mite (Order Acarina) [Correspondence.] *Nature* 1946 June 29 878

Although nearly all workers interested in scrub typhus have tried to breed the trombiculid mites which are believed to transmit the rickettsia little success has previously been achieved. We know that the larval stage must feed on a vertebrate host (viz. a rat) but the nymph and adult living in the soil have given more difficulty and their food has not been recognized. A few have on occasion been reared in various media but it has been obvious that the proper diet has not been discovered. MIYAJIMA and OKUMURA state that *Trombicula akamushi* lives on plant juices but other workers have not confirmed this.

The authors of this communication have for the first time discovered a satisfactory diet for nymphs and adults. They found *Trombicula aculeolaris* larvae parasitizing rats and bandicoots and obtained adults and nymphs crawling on the vegetation choking a pond in which the mosquito *Manxonia uniformis* was breeding. The adult and nymphal mites were found to attack *Manxonia* eggs with avidity and also to feed on *Anopheles* eggs. This mite is clearly carnivorous in its adult and nymphal stages.

Kenneth Mellanby

WHARTON G. W. & CARVER R. L. Food of Nymphs and Adults of *Neoschöngastia indica* (Hirst 1915). *Science* 1946 July 28 76-7

This investigation was very similar to that described by Jayewickreme and Niles (above) but the mite *Neoschöngastia indica* was used. The adults and nymphs were found to feed readily on mosquito eggs and on other insect eggs. They were also noticed to be cannibalistic so this species also is clearly carnivorous.

Kenneth Mellanby

WILLIAMS, R. W. The Laboratory Rearing of the Tropical Rat Mite, *Liponyssus bacoti* (Hirst) *J Parasitology* 1946 June v 32 No 3 252-8, 4 figs.

Work on the transmission of filarial worms in the laboratory has generally been difficult owing to the lack of a suitable arthropod vector. *Liponyssus bacoti* the tropical rat mite is an intermediate host of the filarid *Litomosoides carinii*. This mite is common in the United States, and is easily reared in the laboratory. An artificial rats' nest is made by placing loam soil half an inch deep in a box and a layer of straw above the soil. Rats (either cotton rats or ordinary albinos) in small cages are placed in the box over the straw and soil. The whole arrangement is then stood in a tray of water to prevent the mites from escaping. The soil and straw provide a suitable harbourage for the mites and absorb the rats' urine the production of which is kept at a minimum by giving no water to drink. A high humidity over 70 per cent. (preferably 85-90 per cent.) is recommended [it must approach saturation among the soil and straw]. A room temperature of 21°C. gives good results [again the mites will be in a different warmer micro-climate]. The mites receive no special attention except to ensure that the straw does not become too damp. One such culture started with 32 mites and in a fortnight numbered over 1 000. The female mites lay about 7 eggs after each blood meal they feed approximately every second day. The eggs hatch in two days to give a six-legged larva which moults without feeding in about 24 hours. Breeding is said to be so prolific that the host rats may die from anaemia. [*Liponyssus* might also be used in the laboratory for work on the transmission of murine typhus. It has been shown to be a vector of this rickettsia, in *Rev Applied Entom. Ser B.*, 1932 v 20 49.]

LABORATORY PROCEDURES.

ROGERS K B Oil Sterilisation of Syringes. *Lancet* 1946 July 20 87-8.

The need for scrupulous sterilization of syringes and needles has been widely discussed of recent years and the need is heightened by the recognition of the possibility that non-sterile instruments may transmit infective hepatitis.

Sterilization by hot oil was advocated as long ago as 1921 by WRIGHT and COLEBROOK in their *Technique of the Test and Capillary Glass Tube*.

The author recommends that immediately after use the syringe should be rinsed in water and thus freed of blood. The needle is then removed and the syringe filled three to four times with liquid paraffin at 130° to 140°C. with a second pause at each filling. The needle is replaced and the oil again sucked in and expelled. The sterile syringe is kept in place in a test tube by means of a folded strip of plaster.

The method has the advantage of speed and there is no risk of haemolysis. The heat of the oil should not exceed 150°C as the cement holding the glass to the metal parts may melt. With larger syringes the piston may jam owing to cooling and contraction of the glass but it moves freely again within five minutes. Syringes treated in this way are not sterile on the outside and are thus unsuitable for operating-theatre purposes but are satisfactory for ordinary injections. Oil sterilization does not kill spores contained in dried blood.

The author describes five experiments in support of the oil sterilization method. Cultures of staphylococci streptococci *Bact coli commune* and *M tuberculosis* contained within syringes or in blood which has infected syringes were sterilized by from one to four fillings of oil at 120° to 140°C. Syringe barrels and pistons containing dried blood infected with *Staph aureus* were sterilized by two minutes immersion in oil at 120°C.

Blood containing spores of *B subtilis* was dried in syringes the spores were not killed after 12 minutes in oil at 120°C.

[It is not quite clear why the spores of *B subtilis* were not exposed to the higher temperature ranges before it was concluded that they were not killed by oil sterilization.]

H J O D Burke-Gaffney

LERNER E M A Rapid Gram Stain for Tissue *Arch Pathology* 1946 June v 41 No 6 674-5

The author describes a modification of the Gram stain for the demonstration of bacteria in tissues which he claims overcomes the complications of time labour and inadequate differentiation inherent in the recognized modifications. The method requires less than five minutes of actual staining time and it is claimed gives excellent morphological detail. Bacteria stand out sharply and spore-bearing organisms are recognized readily.

Paraffin sections of Zenker fixed tissues are heated at 56°C. for two to six hours. The actual staining is essentially that of the Gram method for bacterial smears consisting of the conventional crystal violet iodine solution acetone-alcohol, and 1 per cent. safranin as a counterstain. Detailed steps in staining are described in the original paper.

H J O D Burke-Gaffney

DUNN R C A Hemoglobin Stain for Histologic Use based on the Cyanol-Hemoglobin Reaction. *Arch Pathology* 1946 June v 41 No 6 676-7

A cyanol-peroxidase reaction is described which has been found by the author to be highly specific for haemoglobin in paraffin sections of tissue fixed

in 4 per cent. solution of formaldehyde buffered to pH 7.0. The specificity and sensitivity of cyanol as a haemoglobin stain is equal to that of patent blue V in most instances. The actual staining time is about ten minutes. By this method haemoglobin stains blue to bluish grey.

The technique of this method is described in detail.

H J O'D Burke-Gaffney

REPORTS SURVEYS AND MISCELLANEOUS PAPERS.

INTERNATIONAL LABOUR REVIEW 1946 Mar-Apr v 53, Nos. 34 194-9 Land Aspects of Labour Problems in Kenya.

In the Kikuyu territory of South Nyeri, Kenya, the population is increasing at the rate of 2 per cent. per annum. The actual amount of land available was no more than 3.35 acres per family in 1944, which would be reduced to 2.61 acres in 1955; this is insufficient for subsistence. Other land is therefore sought largely by tenant farming, but for various reasons there is little inducement for the tenant farmer to conserve land from which he may be evicted at any time. To augment their income, men seek paid employment away from their homes, leaving their wives to carry out all home farming, and the collection of fuel, which often involves long trips and the carrying of loads sometimes more than 200 lb. in weight. These women are fast becoming mere drudges.

The solution of this problem lies in part in removing a large proportion of the population from the land, and creating a wage-earning group which involves provision for the housing, not only of the men, but of their families, at the places of employment. The general land policy envisaged by the Government of Kenya aims to check soil erosion, to secure the proper use of water and timber resources and to encourage efficient agriculture. "It is on the general standard of living of the people, even more than on the development of production for export, that the economic progress of the colony as a whole must primarily depend. Co-operative farming cannot be undertaken without elaborate preparations—fencing, clearing, provision of water supplies and adequate housing. Moreover, financial help, technical guidance and control by Government are essential before the African adopts effective methods. The natural tendency is towards over-cropping, over-stocking with useless cattle, under-fertilization and failure to conserve the resources. The two important factors are soil-conservation and water supplies, and a scheme to deal with these matters has been approved in principle: this will cost £60,000 in the first year and £600,000 in ten years. It is however realized that greater sums than these will be needed, but it is also known that the effort and expenditure are essential to relieve the over-populated and over-stocked areas and to develop the country so that its people may be healthy and prosperous.

[The effect of these conditions on health are obvious, and in Kenya, as in South Africa, it is evident that the interdependence of the various departments of government is appreciated. The story of the Anchan settlement in Nigeria is apposite in that many departments have collaborated to good purpose, and that a large measure of control is necessary to overcome ingrained habits of inefficient farming, which were of little importance when land was plentiful, but which are dangerous now.]

Charles Wilcocks

GALE G W Health Centre Practice Promotive Health Services and the Development of the Health Centres Scheme *South African Med J* 1946 June 22 v 20 No 12 326-30

The Health Centre system has been adopted as part of the Government plan for improving the health and medical services in the Union of South Africa [see this *Bulletin* 1946 v 43 498-501] and a centre has been in existence since 1940 at Polela, Natal [see this *Bulletin* 1944 v 41 611 1946 v 43 162]. The idea of Health Centre work is not merely to provide a service for those who attend because they are ill but to study all persons in the area, in their homes and by inducing them to come periodically for examination. Both preventive and curative services are provided but the Health Centres will gradually supplant the special clinics. The provision of this service will often if not always depend upon initiative exercised by voluntary agencies. At present there exist in the Union 8 of these centres 3 more are to be started in July 1946 and 9 others in October. Each has now one medical officer one to three nursing sisters and subsidiary staff but eventually there will be in each centre two medical officers a dental surgeon (part time) and increased staff in general. The training of the staffs is being undertaken partly at the former military hospital at Springfield Durban and partly in Health Centres in and around Durban. In June 1946 there were 16 medical officers and 60 health assistants in training.

These Health Centres will not only conduct their day to-day work on the lines indicated they will also be research centres free to conduct experiments to evolve new techniques and to adapt themselves to varying needs. The practice of social medicine and the study of all factors which bear on health will be within their sphere as is indicated by the paper by KARK and KARK to which reference has already been made [this *Bulletin* 1946 v 43 162]. [This work is admirably conceived and the future progress of these centres will be watched with the greatest interest]

Charles H. Slocock

PALLEY A. & BRUWER, T An Analysis of the Medical and Social Conditions of Native Children attending Groote Schuur Hospital Paediatric Out Patient Department. *South African Med J* 1946 June 22 v 20 No 12 339-41

The authors made an investigation into certain aspects of living conditions of 61 unselected African children who attended the paediatric out patient department of the Groote-Schuur hospital. Most of them were under 2 years of age and in most cases the father supported the children though some fathers had deserted their families the parents were interested in the health of their infants and even under adverse conditions were good parents. It seems probable that the infant mortality rate is much higher in these urban Africans than in the Europeans.

Only 42 of the children lived in brick houses the rest lived in shacks 38 houses were fit for human habitation the remainder not. In 34 instances the family (2-10 persons) occupied one room only for living and sleeping. In 45 families the fathers and in 13 the mothers were employed while their children were all the monthly income varied from nothing to more than £15 per month most families receiving from £5 to £10. The authors comment that for a family to exist on less than £10 per month means gross poverty yet 85 per cent of these families did so. Rent was usually up to £2 per month but in 10 families it was between £2 and £5 travel to work by train or bus was necessary for 36 bread winners.

Of these children no less than 21 were suffering from tuberculosis and 17 from other respiratory infections this fact is significant when considered in relation to the housing conditions and overcrowding.

An outstanding feature of the book is its vigorous and stimulating style. The author evidently believes that a book of this kind should provide interesting reading as well as accurate information: he has certainly succeeded in achieving this aim. At the same time he has remembered that his book is an introduction to parasitology rather than a text-book upon it. Emphasis has therefore been laid upon the biological aspects of the subject. We find, for example, that more space is devoted to life-histories, host-parasite relationships, epidemiological problems and to the principles of control and treatment which are based upon these, while relatively less is given to classification, morphology and nomenclature. Brief bibliographies at the end of each chapter introduce the reader to the vast literature on parasitology so that he can readily study in more detail those aspects of it which interest him. At the end of the book there is a list of the leading journals in which papers upon various aspects of parasitology appear and particular attention is called to the *Tropical Diseases Bulletin*, the *Veterinary Bulletin*, *The Review of Applied Entomology*, *Series B*, *The Journal of the American Medical Association*, *Biological Abstracts* and *Helminthological Abstracts*. "The six periodicals mentioned," says Chandler, "on account of their scope and thoroughness are of inestimable value to anyone who attempts to keep pace with the progress of parasitology."

Every parasitologist will heartily endorse this tribute to these invaluable sources of information. Many of them will wish to add a tribute to the value of this book of Chandler's. It is a considerable achievement nowadays to follow in detail and to assess accurately the advances in our knowledge of even one group of Protozoa, Helminths or Arthropods. For this reason, perhaps, some books on parasitology omit either the Protozoa or the Arthropods which are associated with disease and concentrate upon only two of these three phyla, to which most of the animals parasitic in man and his domesticated stock belong. It is therefore especially useful to have in this book an adequate treatment of all these phyla. The biologist too who wishes to relate our knowledge of animals parasitic in man and his domesticated stock to his studies of those parasitic species which have no economic importance will find in this book an admirable fusion of the biological and the economic points of view.

The book is well printed and handy to use. Some of the illustrations could be improved, but most of them are adequate and no doubt it is the author's intention that they should be supplemented by observations made upon actual parasitic animals which cannot be replaced by illustrations, however excellent these may be. There will be some readers nevertheless who cannot take laboratory courses in parasitology and the inclusion in future editions of some of the excellent photographs of parasitic animals which are now available would, no doubt, add to the value of the book. On the other hand, some teachers may prefer the line drawings with which this book is illustrated, because they cannot represent exactly the parasitic animal and therefore do not encourage the student to avoid making his own observations and drawings.

The book can be recommended to both the general public and to the biologist, who will be grateful to the author for guiding the earlier editions into this valuable fusion of readable text and accuracy of complicated information.

G. LaPage

NEVEU-LEMAIRE M. [Professeur agrégé des Facultés de Médecine] *Traité de Protozoologie Médicale et Vétérinaire*. [Treatise on Medical and Veterinary Protozoology] pp. xx + 844 433 figs. 1943. Paris: Vigot Frères Editeurs, 23 Rue de l'École-de Médecine. [45s.]

Like its companion volumes on Helminthology and Entomology (this *Bulletin* 1936 v 33 643 *ibid.*, 1938 v 33 831) this treatise on Protozoology

will undoubtedly be found to be a valuable and convenient book of reference. In fact the reviewer has already had occasion to consult it on several occasions and has obtained references which otherwise he would have had some difficulty in procuring. The book contains a vast amount of information on all aspects of medical and veterinary protozoology, much of it taken from obscure sources which are not frequently consulted, but it is not up to date even if allowance is made for the fact that the date of the author's preface is 1942. Very little reference is made for instance to the developments in knowledge regarding avian and simian malaria and the many species of these parasites including *P. knowlesi* which have come to light in recent years are not mentioned. The importance of the exoerythrocytic cycle in malaria is passed over in a single line. One finds again the old statement that the sporozoite enters the red blood corpuscle. *P. ovale* is merely mentioned in a foot note as being of doubtful validity, while little attention is given to the relationship of the three common human parasites to the similar forms in chimpanzees.

In general the reviewer finds that the book covers very much the same ground as his own *Protozoology*, published in 1926 from which the author has borrowed many figures. The treatise under review however contains much that is not found in the reviewer's book. A considerable amount of space is devoted to consideration of symptomatology, pathology, treatment and prophylaxis of diseases due to protozoa. Over 120 pages are devoted to the intestinal ciliates of domestic animals and their relations—a proportion of the book which seems in excess of their importance. Nevertheless for purposes of reference the account will prove of use. Again under the heading *Treponema*—for as is the custom the spirochaetes and other non protozoal organisms encountered in blood work are dealt with—90 species are mentioned in most cases with reference only to the host. *Rickettsia* and rickettsial diseases receive 35 pages. Finally as in the companion volumes the book has a list of hosts and their parasites, a list of intermediate hosts and vectors and a list of vertebrate reservoirs chiefly mammals. The book is well illustrated with 433 figures and finishes with a fairly good index.

C. M. Wenyon

DUBOIS A. *Chimiothérapie des trypanosomiasés*. [Chemotherapy of Trypanosomiasis.] Institut Royal Colonial Belge. Section des Sciences Naturelles et Médicales. Mémoires (Collection in-8°) 1946 v. 15 No 7 169 pp [258 refs.] [100 fr.]

The scope of this volume is severely limited. Apart from a few introductory sections on general aspects of the chemotherapy of trypanosomiasis it deals in detail only with arsenicals and antimonials, excluding any consideration of mechanisms of drug action or general theory. A second publication is projected to cover non metallic preparations and general theoretical considerations.

In a prefatory note the author writes that the volume prepared during the German occupation served to support him during that painful period, but that the circumstances prevented him from keeping fully abreast of recent literature. Certain additions and alterations will therefore be necessary, but he has felt obliged to arrange for publication before making these changes, because of a journey to Africa. He intends therefore to produce a supplement in due course to set matters right. Those who will wish to use this book will certainly feel that they would have preferred to wait until it could be presented in a more finished form. A number of misprints are corrected in a page of errata at the end of the book, there is no table of contents and most serious of all there is no index. An index is of course essential in a work of this nature which is most likely to be used not as a book to be read from beginning to end, but as a volume to which one will resort, from time to time in reference to a particular compound chemotherapeutic problem, or author.

The introduction reminds the reader that practice based on empiricism, has long preceded theoretical development in the field of chemotherapy (as for example, in the time-honoured use of cinchona bark, mercury etc.) The development of chemotherapy as an exact science was due in large part to researches on trypanosome infections. Whilst LINGARD and BRUCE before the turn of the century may be regarded as pioneers in the empirical chemotherapy of trypanosomiasis and LAVERAN and MESNIL (1902) were the first to embark on systematic experimentation EHRLICH for his labours from 1903 to 1915 is undoubtedly to be hailed as the true founder of experimental chemotherapy. Apart from its outstanding theoretical value his work with trypanosome infections was an essential stage towards the triumphal announcement of the first sound cure for syphilis.

The author writes that his compilation is intended to be of particular service to Belgian colonial medical officers by placing at their disposal the facts known about preparations active against trypanosomiasis, both of man and of animals, and he then recalls with justifiable pride some of the unique contributions of Belgian workers towards the study of trypanosomiasis in the Congo. The Léopoldville laboratory founded in 1899 under the inspiration of General DOUVR turned a major part of its attention to trypanosomiasis at its very inception with VAN CAMPENHOUT as the first Director. His successor BRODEUX (1900-1911) together with RODHAIN developed this interest still further. They conducted numerous field trials of compounds prepared by Ehrlich, and it was they who first introduced the practice of exhibiting tartar emetic intravenously in man. They were also pioneers (1908) in the evaluation of cerebrospinal fluid changes in sleeping sickness. MOCCHET and DUBOIS (1911-1912) were among the first to embark on itinerant mass-treatment, now one of the principal methods of sleeping sickness control. Miss PEARCE and VAN DEN BRANDEN conducted the first field trials of trypanamide, and van den Branden, VAN HOOFF and others have subsequently investigated numerous other products and therapeutic procedures. Human trypanosomiasis which is the chief anxiety of the health service, remains at the present time in the forefront of the Léopoldville laboratory's activities.

The first section deals with general principles underlying the treatment of human trypanosomiasis under the sub-headings of "Intercurrent diseases", "General rules of treatment" and "Follow-up after treatment". There follows a section entitled "Methods of experimental chemotherapy" dealing with experimental procedures in laboratory animals and *in vitro* and including also a consideration of the normal course of infection in untreated human cases. A few pages follow to discuss bismuth, gallium, indium, gold, rhodium and ruthenium, and the work then deals systematically first with arsenicals and then with antimonials.

The arrangement of material presented might perhaps be improved. For example an explanation of the term "Chemotherapeutic index" follows immediately on the section headed "Experiments *in vivo*" instead of being included in the section for "Experiments *in vitro*". Again, having passed on from a general and detailed consideration of arsenicals to a similar treatment of the antimonials one is then brought back to the arsenicals (with section-headings in printing type which would suggest that we are still among the antimonials) for accounts of intrathecal treatment, intracarotid treatment and ocular troubles after arsenical treatment.

Omissions and ambiguities are inevitable in a compilation of this nature especially when prepared under such inauspicious circumstances. It would therefore be ingracious to pick on these particularly when so much is reliably recorded. In any case, the wise reader will of course prefer in his hour of need, to go to the original sources, liberally indicated by the author who does not however

claim to give a complete bibliography and admits to giving special notice to the publications of Belgian workers. His lists together with those given in FINDLAY's *Recent Advances in Chemotherapy* (London Churchill 1939) will guide the reader to all important literature-sources up to the outbreak of the recent war. The most exhaustive lists of references up to about 1834 are probably those in FISCHL and SCHLOSSBURGER's *Handbuch der Chemotherapie* (Leipzig Fischers 1934).

Lest it be thought that this volume is received with unduly faint praise let it be said that we will welcome the second volume and will look forward to placing it on a near by shelf for easy access together with this one—all the more so if it is to include an index to the entire work.

E M Lowrie

FELSEN Joseph [B.A. M.D. Director of Medical Research, Bronx Hospital New York etc.] *Bacillary Dysentery, Colitis and Enteritis*. pp. xiv + 618 145 figs (2 coloured) 1945 Philadelphia & London W B Saunders Company [30s]

This book is a review of our knowledge of all the aspects (clinical pathological and epidemiological) of acute bacillary dysentery, chronic ulcerative colitis and distal ileitis. The author believes that chronic ulcerative colitis and distal ileitis are the late sequelae of acute bacillary dysentery and that their onset can often be traced to an attack of acute dysentery. This opinion is based on experience in the U.S.A. where the incidence of Flexner dysentery and of chronic ulcerative colitis appear to be very much greater than in Britain.

The sections dealing with the symptomatology, diagnosis and treatment of these conditions are clear and up to date. The use of the sigmoidoscope and X-rays in diagnosis and in the control of treatment is advocated and there is a clear account of the sigmoidoscopic findings and radiological appearances in dysentery, colitis and other disorders of the bowel. There is however no mention of the precautions to be taken during the nursing of acute bacillary dysentery either in hospital or at home to prevent the spread of the disease to other persons.

The epidemiological and bacteriological aspects of bacillary dysentery are less satisfactorily described. The author uses the historical approach and frequently quotes the experiences of other workers with too little regard for differences in methods and material. In this way parts of these sections have become merely a confused record of the conflicting findings of others. The description of the bacteriology of the *Shigella* group is no fuller than that given in the standard text-books and is made more confusing than is necessary by the use of an unfamiliar nomenclature, and by the importance given to biochemical rather than to serological reactions. The appendix that gives the technical methods for the isolation and identification of members of the *Shigella* group presupposes that the worker has available supplies of dehydrated media and commercial antisera. Other appendices deal with the control of dysentery in military establishments and in institutions.

The book contains a long and valuable bibliography in which over 2000 references are quoted.

A J H Tomlinson

NORMAN WALKER, J. N. [C.I.E. M.R.C.S (Eng) M.R.C.P (Lond.) D.T.M. & H (Camb)] *Indian Village Health*. pp. iv + 90 8 plans & 2 diagrams Indian Village Welfare Association. 1944 Humphrey Milford, Oxford University Press (Indian Branch) [4s Rs 2-8]

This unpretentious but attractive little book has been written partly as a guide to doctors engaged on public health work, but chiefly with the object

of enlisting the intelligent co-operation of local authorities, voluntary organizations, and the people themselves, in improving health conditions in Indian villages. The author has exceptional qualifications for producing such a book. After a distinguished career in the regular lines of activity of an officer of the Indian Medical Service, he was selected for the important work of reorganizing the medical and health departments of the great State, Hyderabad, in South India, and for a number of years he carried out this task with conspicuous success. He writes, therefore, in the light of practical experience of the problem and deals not with what might be accomplished with the help of ample funds, a highly skilled staff and an enlightened public, but with what can be done in the absence of these advantages. He has confined his attention to the diseases "amenable to general measures in which the assistance of civil authorities and village workers can be really useful, and has strictly avoided the use of technical language.

The causes and methods of control of the chief infectious diseases are dealt with in 45 pages: there is a brief chapter on personal protection against disease, one on the organization of public-health activities, and another on building regulations and the construction of minor public works. In an appendix instructions are given for the control of plague. A special feature of the book is the reproduction of detailed plans of a tuberculosis clinic, an infant welfare centre, a slaughter house, a vegetable market, a meat market, a beef shop, a village well, and an "aqua privy." These plans are reproduced on a very small scale, but they will be found very helpful to officers of health and engineers who have to undertake the construction of such works without previous experience.

The present volume is a reprint of the first edition, which was published in 1943 and probably written in 1942, so that some important recent advances such as the use of DDT are not mentioned.

Although certain details of the methods recommended are open to criticism by experts, the book can be read with profit by everyone who is concerned with the health of villages in India and other tropical countries. It is to be hoped that other public-health workers in the tropics will be stimulated to produce books dealing, on similar lines, with the special conditions of the areas in which they work.

John W. D. Megaw

COWPLAND, Reginald [K.C.M.G. C.I.E. Hon.D.Litt. (Durham) etc.]
Livingstone's Last Journey 271 pp. 5 maps & 2 pls. 1945. London
 Collins, 14 St. James's Place. [12s. 6d.]

Although this book is not primarily of medical interest, readers of this *Bulletin* who have followed the literature on Livingstone, or who desire a succinct account of this period of his life, will be glad to know of the existence of this most readable book. There is evidence of a vast amount of research, but the writing is so clear that scholarship does not obtrude itself, and the story holds the attention of the reader throughout.

A REVIEW OF REFERENCES TO THE BONE LESIONS OF YAWS *

By C. J. HACKETT M.D. M.R.C.P. D.T.M. & H.

Director Wellcome Museum of Medical Science

There are comparatively few articles whose titles strictly refer to this subject and still fewer are based upon the study of the radiographs of more than one or two cases. For purposes of discussion the relevant publications fall conveniently into two groups. The first group includes papers in which bone lesions are mentioned in lists of cases that have received various treatments or are briefly referred to in descriptions of the disease as a whole. The second group comprises papers dealing in more detail with the bone lesions and sometimes including radiographical and pathological data. Seventy-four articles will be discussed but some others that contained nothing original have been disregarded.

The First Group

Of 40 papers falling into the first group in 26 mention is made of bone lesions during the *secondary* stage of the disease in 3 papers such an association is denied but in 11 there are records of various bone lesions occurring during this stage.

HARPER (1917) Fiji, GUTIERREZ (1922) Philippines and HUNT and JOHNSON (1923) Samoa regard all bone lesions as tertiary even (GUTIERREZ) if secondary skin lesions are also present.

Of those who record bone lesions during the secondary stage LENZ (1909) East Africa, speaks of bone and joint pain and MOSS and BIGELOW (1922) Dominican Republic mention swollen and painful joints. The following types of lesions were reported by the other authors —

Periostitis RAT (1891) Leeward Islands HALLENBERGER (1916) Cameroons
 ARAUJO (1928) Brazil HERMANS (1931) Dutch East Indies TODD (1931)
 Belgian Congo D'SOUZA (1933) Nicobar Islands.
 Chronic Periostitis VISWALINGAM (1922) Malaya.
 Osteo-periostitis ARAUJO (1928) Brazil TAKASAKI (1932) Caroline Islands.
 Proliferative osteitis HALLENBERGER (1916) Cameroons.
 Nodes CHAMBERS (1938) Jamaica.
 Dactylitis HALLENBERGER (1916) Cameroons VISWALINGAM (1922) Malaya
 CHAMBERS (1938) Jamaica.
 Arthritis HERMANS (1931) Dutch East Indies TAKASAKI (1932) Caroline
 Islands D'SOUZA (1933) Nicobar Islands.
 Sabre-tibia HALLENBERGER (1916) Cameroons VISWALINGAM (1922) Malaya.

* The material for this review was collected while holding a Senior Fellowship in Tropical Medicine, of the Medical Research Council, Great Britain.

The various bones were reported to be involved as follows —

Skull and clavicle each 3 times scapula, humerus ulna, radius and carpus, once each metacarpals and phalanges 5 times ribs, once sternum, twice femur and patella, each once tibia, 4 times tarsus once metatarsals twice long bones once.

The following references to tertiary bone lesions are made in the same 40 articles. MOSS and BRIDLOW (1922) Dominican Republic, were not sure if tertiary bone lesions were due to yaws or to syphilis. POWELL (1923) Assam, regards all descriptions of tertiary yaws lesions as mis-diagnoses for syphilis. He had seen no such yaws lesions develop among the population whom he had closely observed for ten years following the first introduction of yaws among them. ARAUJO (1928) Brazil, regards all the bone lesions he saw as secondary because secondary skin lesions were present. He had never seen gummata or ulceration due to yaws and does not accept a tertiary stage in yaws. HARLEY (1937) Liberia, does not state the stage of the disease in his cases.

Bone lesions were recorded by the following authors —

Periostitis, acute diffuse localized, generalized multiple or hypertrophic BAHR (1914) Ceylon HARPER (1914) (1917) Fiji BREKID (1915) Papua MOSS & BRIDLOW (1922) Dominican Republic HUNT & JOHNSON (1923) Samoa CALLANAN (1925) Kenya RAMSAY (1925) Assam MONTEL (1928) Cochlin China LAMBERT (1929) South Pacific DEY (1930) Assam WILSON & MATTHEW (1930) Haiti FITZGERALD & DEY (1931) Assam TODD (1931) Belgian Congo HERMANS (1931) Dutch East Indies HARLEY (1933) Liberia DE LANGEN & LICHTENSTEIN (1937) Dutch East Indies MANSION BAHR (1945) STRONG (1944)

Chronic periostitis RAT (1891) Leeward Islands BAHR (1914) Ceylon GUTIERREZ (1922) Philippines CALLANAN (1925) Kenya MANSION BAHR (1945)

Periostitis with ulceration BAERMANN (1911) Sumatra HARPER (1914) Fiji BREKID (1915) Papua WILSON (1924) Haiti STRONG & SHATTUCK (1930) Liberia.

Periosteal nodes HOWARD (1906) Nyassaland GUTIERREZ (1922) Philippines MANSION BAHR (1945) STRONG (1944)

Nodes BREKID (1915) Papua HOWARD (1915) East Africa DEY (1930) Assam D'SOUZA (1933) Nicobar Islands.

Nodes with ulceration HOWARD (1906) Nyassaland LAMBERT (1929) South Pacific

Bone lesions with ulceration CHAMBERS (1938) Jamaica.

Ostitis, hypertrophic diffuse localized or multiple BAHR (1914) Ceylon WILSON (1924) Haiti BUXTON (1928) Oceania MONTEL (1928) Cochlin China WILSON & MATTHEW (1930) Haiti HERMANS (1931) Dutch East Indies DE LANGEN & LICHTENSTEIN (1937) Dutch East Indies SERRE (1938) Belgian Congo MANSION BAHR (1945)

Gummata LEWIS (1909) East Africa VERWALDINGAM (1922) Malaya MONTEL (1928) Cochlin China TAKASAKI (1932) Caroline Islands DE LANGEN & LICHTENSTEIN (1937) Dutch East Indies.

Gummatous periostitis BAERMANN (1911) Sumatra HERMANS (1931) Dutch East Indies.

Gummatous nodes DEY (1930) Assam.

Gummatous ostitis BAERMANN (1911) Sumatra DE LANGEN & LICHTENSTEIN (1937) Dutch East Indies

Periosteal gummata with ulceration RAT (1891) Leeward Islands HALLER HERGER (1916) Cameroons HERMANS (1931) Dutch East Indies TAKASAKI (1932) Caroline Islands DE LANGEN & LICHTENSTEIN (1937) Dutch East Indies.

Dactylitis RAT (1891) Leeward Islands CASTELLANI (1907) Ceylon LENZ (1909) East Africa BREINL (1915) Papua de BOISSIERE (1917) Fiji HARPER (1917) Fiji MOSS & BIGLOW (1922) Dominican Republic CALLANAN (1925) Kenya BUXTON (1928) Oceania DEY (1930) Assam STRONG & SHATTUCK (1930) Liberia WILSON & MATHIS (1930) Haiti TODD (1931) Belgian Congo HARLEY (1933) Liberia DE LANGEN & LICHTENSTEIN (1937) Dutch East Indies SERRA (1938) Belgian Congo MANSON BAHR (1945) STRONG (1944) MACKIE *et al* (1945)

Sabre-tibia CASTELLANI (1907) Ceylon BAHR (1914) Ceylon WILSON (1924) Haiti BUXTON (1928) Oceania DEY (1930) Assam WILSON & MATHIS (1930) Haiti HERMANS (1931) Dutch East Indies TAKASAKI (1932) Caroline Islands D'SOUZA (1933) Brazil HARLEY (1933) Liberia DE LANGEN & LICHTENSTEIN (1937) Dutch East Indies SERRA (1938) Belgian Congo MANSON BAHR (1940) STRONG (1944) MACKIE *et al* (1945)

Epiphysitis WILSON & MATHIS (1930) Haiti MANSON BAHR (1945)

Spontaneous fracture MANSON BAHR (1945)

The various bones were reported to be involved as follows —

Skull 11 times clavicles 10 times scapula and humerus each once ulna and radius each 12 times metacarpals and phalanges 7 times hand bones twice ribs 7 times sternum 10 times vertebrae once femur twice tibia 18 times fibula, twice metatarsals once foot bones once limb bones 7 times

The foregoing summaries may be amplified by the following notes —

BAHR (1915) Ceylon, observed hard bony nodules resulting from the subsidence of periostitis and diffuse osteitis leading to sabre-tibia and often bowing of the forearms. Apparently a rarefying process occurs in the centre of long bones leading to spontaneous fracture and mal-union. Epiphysitis of phalanges and metacarpals leading to deformity and shortening of digits was noted and one case of ulceration obviously associated with bone lesions. HARPER (1914) Fiji speaks of perichondritis of the costal cartilages the same author (1917) Fiji, records that 15 per cent of 542 tertiary cases had bone lesions and that 75 per cent of these involved the lower limb. BREINL (1915) Papua apparently reports only tertiary yaws bone lesions and would regard some of them as a separate disease. Illustrations depict absorption of phalanges and ulceration of legs probably related to bone lesions. HOWARD (1915) East Africa reports that in children stunting or overgrowth of the ulna may lead to dislocation of the hand. GUTIERREZ (1922) Philippines found sub-periosteal nodes which altered the size and shape of the bone. periostitis was present in over 40 per cent of cases of tertiary yaws. WILSON (1924) Haiti saw the femur affected only once and thought the humerus ribs and vertebrae were exempt.

BUXTON (1928) Samoa, observed ulceration with osteitis. He regarded bone lesions as tertiary for he saw few cases of primary or secondary yaws since recent systematic mass treatment had been moderately effective. MONTEL (1928) Cochun China observed ossifying periostitis with eburnation, but more often he found such destructive processes as osteo-chondritis osteoporosis with rarefaction of osseous trabeculae or rarefying osteitis purely localized gummatous forms led to bony destruction and punched-out perforations of bones which were well seen in radiographs. He thought tertiary yaws lesions less frequent and more benign than tertiary syphilitic lesions. LAMBERT (1929) South Pacific, says that if periosteal nodes occur near the middle of a bone they cause bending. If at the ends in young people they lead to lengthening of the bone. Necrosis of bone is in his experience rare. In 1423 cases WILSON and MATHIS (1930) Haiti found rheumatic pain in 48.8 per cent, painful swollen joints in 4.7 per cent periostitis and osteitis in 4.7 per cent, dactylitis in 0.5 per cent sabre-tibia in 0.4 per cent.

DEY (1930) reported deformity of fingers and shortening of phalanges. STROM and SHATTUCK (1930) Liberia report dactylitis with or without ulceration and bony destruction. TOND (1931) Belgian Congo says that the periostitis of the secondary stage may accompany or precede the generalized skin eruption. TAKABAKI (1932) Caroline Islands, speaks of diffuse or circumscribed thickenings of the tibia and other bones, immediately beneath the skin. HARLEY (1933) Liberia, found bone lesions in 28 per cent. and rheumatic pain in 56 per cent. of 5,597 yaws cases; he also observed bowing of the forearm bones. He concludes that there are apparently two types of advanced active yaws: one characterized by ulceration of the skin and soft parts and the other by rheumatic pain and involvement of the bones. DE LANGEN and LICHTENSTEIN (1937) Dutch East Indies, speak of a diffuse osteitis and periostitis especially of the tibia, leading to thickening and bowing and thus to sabre tibia. SERRA (1938) Belgian Congo says that tertiary yaws bone lesions resemble those of syphilis and that the general health is usually good. He also noted irregular thickening of the tibia and hypertrophy of the femoral condyles. Parts exposed to frequent injuries were most often affected. FOX (1944) speaks of osteoperiostitis of the long bones especially the tibia, ulna, fingers and clavicle and synovitis and tenosynovitis as occurring in the tertiary stage. He does not mention secondary bone lesions.

The Second Group

The 34 remaining articles to be discussed deal with the bone lesions of yaws in more detail, and many of them are based on some radiological or pathological data. With one or two exceptions they will be dealt with in chronological order.

SCHUFFNER (1907) Sumatra speaks of bone and joint pains worse at night which were sometimes marked in the first six months of the disease; adults suffered more than children. Although these pains were present in 20 per cent. of cases he found no radiographical changes. They occurred in the first eruption or during relapses but later in the disease they were less evident. They could not be differentiated from the pains of syphilis except that they were more severe and frequent. Mercury was most effective in their treatment. He found thickening of the bones of the extremities without spontaneous pain in 4 of 63 adults and in 13 of 66 children under 14 years of age; all these 13 had the typical generalized yaws skin eruption. He reports periostitis of the middle and index fingers, fifth metatarsal, ulna and fibula causing swelling of the part. He found no rarefaction of bone tissue although his illustrations show rarefied foci in the periosteal deposits. On healing the affected bones returned to normal. He claims that the periostitis is like that of syphilis but that its localization to only part of a long bone, the absence of pain, and its onset in children allow of certain differentiation. These changes are not related to gummata of bones and respond well to mercury.

BAERMANN and SCHUFFNER (1912) Dutch East Indies regard the periostitis of the early stage of yaws as characteristic and especially frequent in children. They point out that even in the early stage of the disease lesions are not confined to the skin. In the tertiary stage there may be enormous osteitic and periostitic thickening of the tibia and bone lesions with gummatous-cystic formation.

A paper by MALL (1918) Philippines, is frequently and uncritically quoted. He describes 10 out of 20 cases with bone lesions found in 100 cases of yaws. The initial diagnosis of bone lesions in these cases was apparently based upon the complaint of pain. He publishes illustrations of only 4 of the cases. The radiographs reproduced of his "type" case are poor and suggest periosteal deposits along the radius and ulna which are not in his descriptions. Secondary

yaws skin lesions were present only in his type case a woman aged 27 with yaws of 5 months duration in the other three cases the skin lesions had healed 9 months to 5 years previously One of these patients aged 15 had contractures and large ulcers and the radiographs resemble what other writers would describe as early gummata. In another patient aged 15 he illustrates small areas of rarefaction in the articular surface of the tibial epiphysis and cortical thickening periosteal deposits and small cortical rarefied foci of the phalanges with some destruction. In the fourth case there was one small cortical rarefied focus in the calcaneum. The illustrations of Maul's type case show well-defined large oval foci up to 2-3 cm in length of cortical rarefaction in and on the surface of the cortex of the radius and ulna with probably little or no periosteal reaction Maul says that most of the lesions appear to originate in the interior of the bone but this cannot be determined from the illustrations In the hand bones are shown small cortical rarefied foci and some periosteal deposits which apparently resolved with treatment. The nodular lesions which he reports in 2 per cent. of cases and the chronic lesions which he says differ from the earlier ones are not mentioned in his case notes His illustration of chronic bone lesions with deformity is probably of lesions of tertiary yaws but he gives no details of the case He differentiates yaws bone lesions (excluding the 2 per cent. nodular ones) from syphilitic by the absence of both periosteal proliferation and cortical thickening in the former In the nodular lesions the thickening remains localized and sooner or later shows central rarefactions thus becoming the periosteal gummata of other authors. In Maul's 20 cases the frequency of involvement of bones was as follows—tibia 8 fibula 7 calcaneum and phalanges of hands and feet each 6 metacarpals and radius each 4 humerus and patella each 3 ulna femur and tarsus each 2 carpus ribs scapula, sternum and pelvis each once Lesions of vertebrae and clavicle were not observed. He concludes that in his series the joint pains were due in the most part to the presence of lesions of the articular surfaces although of his 20 cases 7 had only 2 lesions and 5 only 1 lesion in the whole skeleton. He concludes that regeneration of the bone is complete at the site of the lesion if the destruction has not been too great.

FERNANDEZ (1917) Philippines at the meeting when MAUL (1918) read his paper showed a radiograph of yaws lesions of the vertebrae but no illustration is published.

VAN NITSEN (1920) Northern Rhodesia says that osteocopic pains occur in the secondary and tertiary stages Of 699 yaws cases 459 had tertiary yaws lesions among which the following bone lesions were observed osteitis and periostitis including thickened long bones sabre-tibiae exostoses and dactylitis (77) bony necrosis from extension of yaws ulcers (27) bony rarefaction and absorption of phalanges (3) Van Nitsen does not mention gummatous lesions although his cases of bony necrosis were probably of this nature He says that tertiary lesions may occur at any age even in infants of 18 months and that the tertiary period starts towards the end of the secondary stage either with a relapse of the eruption or 10-30 years after the secondary lesions have healed.

CLAPIER (1921) French Equatorial Africa reports that the hypertrophic osteitis of yaws appears in children when the secondary rash has been general used for some months often when it is subsiding but some typical yaws are usually still present The principal lesions are (1) goundou (2) osteitis of the short bones e.g. scapula trapezium scaphoid, etc (3) osteitis of the epiphyses of long bones (4) osteitis of the diaphysis of long bones with changes in length thickness and form which may be either localized or generalized (sabre-tibia) The phalanges are often swollen. These changes are rarely single are usually bilateral and are always accompanied by simple muscular

atrophy. In the Oubangui Clavier found that in 10 per cent. of 600 yaws cases there were bone lesions. These became less marked as the bony system developed, but permanent deformities resulted in half the cases. He rules out rickets and congenital syphilis as causative factors. He regards yaws osteitis as a tertiary lesion which nearly always encroaches on or prolongs the secondary stage.

SPITTEL (1923) Ceylon describes periosteal nodes and bony tenderness in the secondary stage but says they belong more appropriately to the tertiary period. As tertiary bone lesions he describes localized gummata or nodes which may ulcerate and diffuse periostitis and osteitis leading to osteosclerosis with bowing and deformity of long bones (sabre-tibia). Central gummata of the phalanges and absorption of these bones with shortening and ankylosis may also occur. No bone is exempt, but sites of muscular attachments are particularly affected. SPITTEL found the vertebrae involved in one case.

GUERRERO FERNANDEZ and ROSAL (1924) Philippines describe the case of a girl aged 13 who had had yaws for 6 months. The radiographs showed cortical thickening and small foci of cortical rarefaction in the proximal phalanges and metacarpals which healed under treatment with sodium-potassium tartrate-bismuthate.

MAYER (1924) quotes SCHIFFNER's description of the early bone lesions of yaws and says that the later lesions consist of large osteitic and periostitic thickenings of the tibia with deformity and also bony craters with gummatous cystic changes.

PLENN and MEYER (1924) state that painful periostitic rarefactions sometimes combined with proliferating osteitis occur in the secondary stage. In the tertiary stage gummata on the sternum near the clavicle are characteristic. Periostitis and osteitis sometimes with gummatous ulceration of the soft tissues are also seen and in children may lead to gross deformity.

BOTREAU-ROUSSEL and CORNIL (1924) describe the histopathological changes in specimens of goundou. These consisted of thickening of the periosteum and hypertrophy of the spongy tissue with increased trabeculae. There were also fibrous and perivascular plasma-cell collections in the spongy tissue. These were comparable with certain syphilitic changes and indicate that in yaws as in syphilis, the bone marrow is particularly liable to attack.

BOTREAU-ROUSSEL (1925) Ivory Coast, found that 75 per cent. of 130 cases of yaws osteitis occurred during or soon after the generalized skin eruption. Of these 130 cases, goundou was present in 121 and the tibia was involved 69 times, the fibula femur radius ulna clavicle humerus and phalanges were involved one to five times each. He describes cases of goundou with thickening of phalanges and long bones and the development of sabre-tibiae during or soon after the yaws eruption. In this group of 130 cases the bone lesions appeared while the secondary eruption was present in 49 per cent. (64) and soon after the eruption had healed in 33 per cent. (43). He regards these as tertiary lesions occurring during the secondary stage (see his Fig 1). In the long bones hypertrophic osteitis was present. The periosteum was thick and adherent to the bone, the surface of which was very rough and irregular owing to the enormous dilatation of the Haversian canals whose external openings were up to 2 mm. in diameter giving the bone a spongy appearance. The medullary canal of a sabre-tibia on section was completely filled with irregularly alveolar tissue, transversely the bone was circular. Anterior bowing of the femora was also seen.

SORTOMO and EICHHORN (1925) Dutch East Indies say that except for periostitis most of the bone lesions of yaws are tertiary and resemble those of tertiary syphilis in the symmetry of their occurrence and in the sites of predilection—e.g. the occurrence of gummata in the tibia forearm bones and cranium.

They point out that there is a fairly constant bony rarefaction surrounding the yaws lesion so that often there is gummatous softening with hyperostosis and sclerosis surrounded by atrophic changes. The bony rarefaction is apparently connected with neurotrophic disturbances and the resulting diminished rigidity probably leads to the deformities so often seen in *framboesia* particularly in growing bones. The atrophy remains for some time after the healing of the yaws process. There is no bony atrophy in syphilis. Gummatous osteomyelitis a rarity in syphilis is not infrequent in yaws and the cortex and periosteum show little reaction so that spontaneous fractures or total necrosis may occur. The final diagnosis of tertiary yaws bone lesions may depend on the history, symptoms and locality. The Wassermann reaction is usually strongly positive and is rarely changed by treatment with salvarsan and mercury. The illustrations to this paper show large foci of rarefaction with localized periosteal deposits, sabre-tibia, a spontaneous fracture, indefinite cortical rarefied foci in phalanges, calcaneal changes and total necrosis of the humerus following gummata.

KNAGGS (1926) states that in yaws as in syphilis the bones are affected in the tertiary stage. He quotes MAUL (1918) and says that Maul's illustrations do not resemble syphilitic lesions. He describes a tibia from New Guinea (in the Royal College of Surgeons Museum, England) which he compares with the lesions Maul describes and he suggests that the lesions present were probably associated with ulceration. The pitted condition he regards as quite different from the usual appearances of syphilis of long bones. Other authorities would regard these lesions as multiple gummata.

HASHIKUCHI (1927) describes the cases of 5 children who had yaws two or more years previously and were incompletely cured. They all had positive Wassermann reactions even after the bone lesions had cleared up under treatment. All had dactylitis and in 4 cases the long bones were affected. The terminal phalanges of the hands and the middle and terminal phalanges of the feet were not affected. One patient had slight nocturnal pain. Histo-pathological changes in material from the biopsy of one phalanx are reported. The periosteum was thickened and oedematous with slight diffuse cellular infiltration of lymphocytes, plasma cells, fibroblasts and polymorphonuclear leucocytes near dilated small veins (sic). Indeterminate vascular changes were present. No necrotic or cicatricial changes and no spirochaetes were seen.

POLAK (1927) Java says that the bony changes of yaws occur chiefly in the tertiary stage but they may appear early even in children, and their differentiation from congenital syphilis is difficult. Periostitis and osteitis are the most frequent changes. Long and short tubular bones may be affected, but the tibia is most frequently attacked often resulting in sabre-tibia. He describes the case of a boy aged 15 who had yaws in infancy and when seen had tendon contractures, ankyloses, tertiary ulcers, osteomyelitic foci with ulceration and spontaneous fractures and sabre tibiae. The Wassermann reaction was positive and the active lesions responded quickly to neosalvarsan. He found that the X-ray pictures resembled those of tertiary syphilis. Symmetrical gummatous processes were found in the tibia, ulna and radius and the carpal and tarsal bones. The bones of the fingers and toes were also affected. In favour of yaws was the severe bony rarefaction, gummatous and atrophic and the scanty cortical and periosteal proliferation. Cachexia is less frequent and the viscera are very rarely attacked in yaws. The history and clinical findings assist in the diagnosis of yaws.

SCHOEHL (1928) Philippines writes it is an open question whether or not the bone lesions in yaws either early or late are always due to actual localization of *Treponema pertenue* in the bones or whether it is a process analogous to that of keratoderma plantare which he found occurred in monkeys in a

state of partial immunity. He says that bone lesions should be classified by themselves since they are either early or late hypertrophic, atrophic or necrotic, and may affect the periosteum or bone. In a private communication (1935) he says that in nearly 500 monkeys experimentally infected with yaws he found bone lesions developed only as an extension from skin lesions.

FOX (1929) Haiti, speaks of unilateral osteo-periostitis with fungating cutaneous gummata of the leg indistinguishable from those due to syphilis. He illustrates an inactive lesion consisting of a dense localized cortical thickening on the anterior surface of a bowed tibia.

HASSELMANN (1931) Philippines, who had worked with SCHORAL, says rarefying osteitis and periostitis although claimed by clinical observers as an early manifestation of yaws have never been observed in experimental infections in man or monkeys. Neither pathological changes typical of yaws nor *Treponema pertenue* have been found and it has yet to be proved that the bone lesions are not an extension of a previously healed skin lesion.

MONTÉL and COUPUT (1932) Indo-China do not mention bone lesions during the secondary stage. They found osteo-periostitis in 10-20 per cent. of cases of tertiary yaws. It was most frequent in children and adolescents and in conditions of malnutrition. It appeared 3-6 years after the secondary eruption. The limb bones were usually affected, but the ribs clavicles and all other bones might be involved. Clinically these authors recognize two forms—(1) localized nodular lesions with gumma like "gêodes" (2) diffuse osteitis, due either to extension of the nodular lesions into the cavity of the bone or to the original involvement of the cavity which leads to destruction of the periosteum, to hypertrophy or more often to rarefaction of the cortex and trabeculae and also to osteoporosis. Ulceration, they say may occur in both types. The lesions develop slowly without marked general symptoms except profound osteocopic pain but cachexia may result. Arthritis, ankylosis and sabre-tibia may occur. Response to neosarsphenamine is good. Differentiation from syphilis is assisted by the presence of yaws in the community and by the history of the patient. Syphilitic bone lesions are probably never so generalized as yaws bone lesions and in the latter the periosteal proliferation and cortical thickening so characteristic of syphilis are lacking. In 30 years in Cochinchina MontéL and Coupout saw only one case of goundou and in Indo-China where yaws is prevalent they saw none. They note the resemblance between the limb bone lesions described by BOTREAU ROUSSEL (1925) and those they have seen in yaws cases. They suggest that goundou is a special aspect of African yaws and gangosa of Philippine and Malayan yaws. The illustrations show large foci of cortical rarefaction either isolated or in groups with bony expansion and some periosteal deposition. In the phalanges are small foci with cortical thickening. The osteoporosis and trabecular changes are not well shown.

BEITZKE (1934) says that differentiation of yaws from syphilitic bone lesions is difficult. In yaws osteoporosis is usually present and periostitis is found during the secondary stage. Tertiary bone lesions may occur early even while secondary skin lesions are still present—they are periosteal and osteomyelitic gummata, which are usually localized, though numerous foci may exist in one bone. These lesions produce only slight bone formation. Spontaneous fractures are more frequent than in syphilis and callus formation is slight. Periosteal and cortical gummata frequently ulcerate. The same bones are affected as in syphilis the skull and tibia most frequently but also the phalanges metacarpals metatarsals ulna and fibula. In the tibia, hyperostoses with sabre-tibia also occur. Sabre-tibia is more frequent in yaws than in syphilis. Contractures and ankyloses are also found.

MONTEL, MASSARI and LE VAN PHUNG (1934) Annam describe the case of a boy aged 15 who had yaws 9 years previously with bone lesions of several years duration. The affected parts were swollen and on the legs gummatous ulceration extended to the bone. Two types of lesion were seen in the radiographs (1) localized diaphyseal thickenings with condensation of the periosteum and deep tissue encircling the bone or on one side only and (2) géodes [gummata] of various sizes but always round and well-defined in these thickenings and associated with further marked condensation. Between these last lesions there might be slight decalcification. The authors say that the number of the géodes the irregularity of the hyperostoses and the narrowing of the medullary canal, differentiate these yaws lesions from those of syphilis. The illustrations are good and show expansion cortical thickening and large foci of cortical rarefaction in the bones of the forearm.

WOLTER (1934) concludes from the absence of spirochaetes in them that the lesions of the phalanges in yaws are an allergic reaction to the organism. He also suggests that the absence of spirochaetes in these lesions may be due to framboesial spores such as have been assumed in syphilis but he admits that this does not account for the predilection for the phalanges.

The *Jamaica Yaws Commission Report* for 1936 states that there are probably some bone lesions in the majority of cases of yaws in the early stages with pain and tenderness. Perhaps 15 per cent. of yaws cases have bony swelling and tenderness. The long bones especially of the forearm and leg are most frequently affected but the skull phalanges or any other bone may be involved. Bone changes are perhaps most frequent during the secondary stage but they also occur later and may be associated with ulceration. The course of localized swelling fluctuation and ulceration has been observed. Great deformity frequently results and also bowing of the legs and forearms. The radiographical appearances are fairly constant and often characteristic (1) widespread multiple areas of rarefaction with or without surrounding increased density and (2) fusiform enlargement due to periostitis causing thickening of the cortex or (3) great enlargement with sclerosis of cortex and medulla. The Report for 1932 states that no spirochaetes were found in material collected from bone lesions.

HACKETT (1936) Australia traces part of the development of sabre tibia and describes certain other lesions found in aboriginal bones which he suggests are due to yaws. No account was taken of the stages of the disease in which the lesions occurred. Secondary skin lesions were rarely seen. All the lesions that were suggested to be of yaws origin have been described by observers in yaws communities.

MACKAY (1938) criticizes the suggestion of HACKETT (1936) that certain lesions in aboriginal bones are due to yaws. He describes and illustrates a number of the 350 specimens he examined in the Australian Institute of Anatomy Canberra and divides the bony changes he observed into periostitis osteitis with rarefaction and sclerosis and osteomyelitis. He concludes that they result from venereal syphilis an endemic type of non venereal syphilis or some unknown indigenous disease. He regards venereal syphilis as the most probable. [Excluding the fractures and joint and skull changes many other lesions strikingly resemble the bone lesions of yaws reported in yaws communities and observed by Hackett in Uganda. MACKAY's exclusion of yaws as a possible cause is based upon published accounts of disease in Australian aborigines without apparently any observations or enquiries by himself concerning the diseases at present occurring in isolated aboriginal communities. The only articles on yaws bone lesions to which he refers are SPITTEL (1923) KNAGGS (1926) and P. MANSON *Tropical Diseases* (no date).]

BOTREAU ROUSSEL, FRAGES and GAUTHIER VILLARS (1937) Ivory Coast, describe the histopathology of yaws bone lesions in specimens from 20 biopsies. The main changes were thickening of the periosteum, in which were small collections of lymphocytes and plasma cells. They also observed vascular sclerosis decalcification laminar absorption and osteoclasts. There were increased fibrous tissue and plasma cell infiltration in the medullary spaces. Giant cells, marked bony destruction and spirochaetes were not found. These authors could not describe any changes as characteristic.

BOTREAU-ROUSSEL (1937) Ivory Coast regards all the bone lesions of yaws as secondary lesions. Pain is present in most cases of secondary yaws at some time. Clinically there is no difference between the bone lesions (osteopenostitis) at the onset and the deformities found years later. He never saw necrotic excavated lesions or gummatous nodules with ulceration such as those described by MONTIEL in Indo-China. The onset, he says may be abrupt or gradual with swelling over the bone tenderness and increase of the pain which is worse at night. General symptoms may be absent. Over 40 per cent. of 75 cases under 2 years of age had obvious bone lesions. In 130 cases the following bones were affected—phalanges, 36 per cent. metacarpals and ulna each 15 per cent. tibia 14 per cent. radius 12 per cent. fibula, 5.5 per cent. femur humerus and others each 0.5 per cent. skull, 0.2 per cent. foot bones and goundoun each 0.15 per cent. BOTREAU ROUSSEL states that fingers may be swollen and turgid, the long bones thickened or fusiform and, in advanced cases deformed by exaggeration of normal curves or by exostoses. Severe pain may last months or years but osteitis may continue after pain has ceased. In the hand, joints may be involved and spontaneous fractures occur with resulting deformity. Ankyloses mal-union of spontaneous fractures and sabre-tibia may result. Diffuse or localized swellings of the skull are found. Soft tissue changes resolve and leave the bony thickenings more obvious. The histopathological changes are those he described earlier (1924 and 1937). In early cases the periosteum is thickened and the bone soft the bone is spongy from dilatation of the Haversian canals which, in marked cases are filled with fibrous tissue. In old cases the cortex is dense and hard. In radiographs the periosteum is seen to be loosened and separated by inflammatory tissue this phase is soon followed by thickening of the underlying cortex and reaction of the medullary tissue so that fusiform thickening of the bone and narrowing of the medulla result. In advanced lesions the Haversian canals considerably enlarged by fibrous tissue give the swollen bones the lacunar appearance of fibrous osteitis. Later there is organization and bone is deposited round the enlarged Haversian canals. This author discards the suggestion that poor resistance or malnutrition plays an essential part in the production of bone lesions. His illustrations show sabre-tibia periosteal deposits expansion and cortical thickening and small foci of cortical rarefaction which he attributes to dilated Haversian canals.

CARTON (1937) French Colonies says the transition from the secondary to the tertiary stages is more theoretical than real. During the secondary stage rheumatic joint and osteocopic pains periostitis and dactylitis occur and in the tertiary osteopenostitis, bony deformity contractures and ankylosis. These tertiary lesions may appear while the secondary lesions are still present, but more often they develop 2-8 years after infection or even after a latent period of 30 years. It is difficult to differentiate tertiary yaws from syphilitic lesions and figures for their incidence are of doubtful value as there is so often confusion. Carton refers to MONTIEL, COUPOT and BOTREAU ROUSSEL for descriptions of yaws bone lesions. The incidence of tertiary yaws lesions is higher where the incidence of yaws is highest hence he is prepared to consider a tertiary stage in yaws and not to regard these lesions as syphilitic as he did until recently.

SIMPSON (1938) *Cameroons* does not mention bone lesions during secondary yaws. Tertiary bone lesions commence five or more years after the secondary stage. The onset is indicated by pain and a small tender swelling. Radiographs show the periosteum raised from the cortex. This process extends along the bone. Decalcification of the underlying cortex follows causing a moth-eaten appearance and calcification of the periosteal changes takes place finally diminished vascular supply leads to bony sclerosis. Ankylosis and ulceration may occur. The apparent bending of the tibia according to this author is due to periosteal deposits on the anterior surface and not to deformity of the long axis of the shaft. There were no cases of sabre-tibia in 920 cases of yaws seen by himself nor in the 30 000 yaws cases dealt with by 80 African yaws attendants. He suggests that some diietic deficiency is the cause of this deformity. He says the whole of the pathology of yaws is confined to the surface of the body the skin and superficial bones being the chief sites of the lesions e.g. the leg forearm and clavicle. Post mortem examination of 20 cases of suspected yaws showed osteitis with varying degrees of rarefaction and sclerosis of bone. His illustrations which are poor show periosteal deposits cortical thickening and expansion and cortical rarefaction and periosteal deposits.

BRYANT and FAIRMAN (1939) Sudan say that bone lesions in yaws are common in Nilotics (Dinka Shilluk and Nuer) and uncommon in forest dwellers (Azanda Bongo and others).

WILLIAMS (1939) in a recent text book of X ray diagnosis quotes only from MAUL (1918) KNAGGS (1926) and WILSON and MATHIS (1930) and repeats the confusion of comparing the New Guinea tibia (R.C.S. England) with the changes described by MAUL.

GOLDMANN and SMITH (1943) from a study of 101 cases in African soldiers and civilians at Sierra Leone stress the difficulties of differential diagnosis.

Diagnosis of yaws was based upon the presence of typical yaws scars quick response to treatment and the positive Kahn reaction. The following frequency of bone involvement was observed the tibia in 46 cases fibula in 20 femur in 13 ulna in 10 humerus in 9 radius in 7 and other bones each in less than 5. The authors illustrate a vertebral lesion and report skull lesions and spontaneous fractures. Gummata were noted especially in the ribs clavicle and pelvis. Trauma was considered an important factor in imitating lesions. During active growth joints and epiphyses are attacked.

The first sign of activity is said to occur in the cortex and resembles the lesions described by MAUL (1918) or are of more moth-eaten appearance. The later stages they regard as either heavy thickened bones or shrunken bent ones.

They believe the absence of periosteal deposits in the presence of cortical lesions [the bony expansion they described must have arisen from the periosteum] and the frequency of fibular lesions in yaws differentiate it from syphilis. Other lesions that might lead to confusion are osteomyelitis osteitis deformans and tuberculosis. [It is probable that the authors refer only to tertiary bone lesions they do not mention any secondary bone lesions.]

HELFET (1944) deals with acute bone lesions in West Africans mostly soldiers. In all cases the Wassermann and Kahn reactions were positive. He regards trauma as often initiating the lesions which soon develop marked changes. Acute onset with rheumatic pain and fever was frequent. The tibia femur clavicle and humerus were most frequently affected, but vertebral and skull lesions occurred. Joints and tendon sheaths were also involved. He says that yaws bone lesions are more rapid in development and are more painful than syphilitic ones.

X-ray appearances were increased diameter and density of bones or multiple layered periosteal deposits over diffuse cortical rarefactions. Microscopically

the bone lesions resembled syphilitic lesions except for the absence of endarteritis [In this paper too probably only tertiary lesions are described.]

ASH and SPITZ (1945) regard bone lesions as tertiary. They say the tibia is most frequently involved and the early lesions are small foci of cortical rarefaction which lead to a diffuse worm-eaten appearance of the entire shaft. The resulting weakening of the bone leads to sabre-tibia. They speak of the development of "marble bones" in which fracture easily occurs. Gummata may occur in flat bones but are seldom in long bones. In children epiphyses and joints may be affected. The absence of periostitis in the presence of osteoporosis in yaws differentiates it from syphilis. They include goundou and gangosa in the tertiary stage [Their illustrations of lesions of the hand bones are almost certainly secondary not tertiary]

Summary

The 70 articles dealt with above although not including every reference to the bone lesions of yaws are representative of the literature of this subject. The first point that comes to notice is the absence of any complete radiological study of these lesions. French and Dutch authors have added most to the knowledge of the subject since the earlier work of SCHÜFFNER (1907) and MAUL (1918).

Many of the differences in the various descriptions are probably due to the incompleteness of the studies upon which they are based, but it is remarkable that BOTTEAU-ROUSSEL (1937) Ivory Coast, saw no destructive bone lesions comparable with those described by MONTÉL *et al.* (1932 and 1934) Indo-China. SOETOMO and EICHORN (1925) and POLAK (1927) Dutch East Indies, HACKETT (1936) Australia, and by others in other parts of the tropics who had made no radiographs. Although these "bony gummata" were described in other parts of Africa by HOWARD (1908) Nyasaland LEWIS (1909) East Africa HALLENBERGER (1916) Cameroons and probably SIMPSON (1933) Cameroons no radiological evidence has been produced.

Another feature of the literature is the absence in many articles of any reference to bone lesions occurring during the secondary stage of yaws while some authors maintain that all bone lesions belong to this period of the disease others state that they are all tertiary lesions. Here again there is no definite geographical grouping to account for the differences found. In the series of cases studied in Uganda by the reviewer and to be reported elsewhere lesions were found in all stages of yaws and practically all the lesions described above were observed.

MALARIA.

CALDWELL, J. D. *Malaria Control in the Dominican Republic. Puerto Rico J Pub Health & Trop Med.* 1945 Dec v 21 No. 2, 193-200 [Spanish version 201-8.]

The Dominican Republic (Santo Domingo) occupies the eastern two-thirds of the island of Hispaniola (Haiti) lying to the east of Cuba and Jamaica in the West Indies. The climate is typical of the Caribbean region with a rainy season between May and October heaviest in the spring and autumn and totalling 100 inches per annum in some parts. Malaria is prevalent varying in intensity in different communities: spleen rates vary from 0 to 42.8 per cent. Among 1,574 positive blood smears 72.8 per cent. showed *Plasmodium falciparum* 17.18 per cent. *Plasmodium vivax* 4.73 per cent. *Plasmodium malariae* and 5.61 per cent. mixed strains. *Anopheles albimanus* is the principal malaria vector. Streams are the main breeding places, but swamps, lagoons and irrigation systems may also be involved. A Malaria Division of the Health Service was formed in 1941. In relation to certain urban areas where seasonal clinical malaria occurs permanent major and minor drainage schemes have been instituted. The author states that requisite personnel are being trained and that larvicidal control is to be commenced.

BERBERIAN D A The Species of Anopheline Mosquitoes found in Syria and Lebanon. Their Habits, Distribution and Eradication. *J Palestine Arab Med Ass* 1946 July 1 No 5 120-46 1 map & 10 figs [Numerous refs]

To enable the reader to understand the problem of anophelism in Lebanon and Syria the author outlines the main topographical and climatic features of the territory. He then gives an account of the morphology, distribution and habits of the anopheline mosquitoes, comments on their importance as vectors of malaria and discusses the possibility of their eradication from the country.

Two mountain ranges run parallel to the sea coast: the western range comprises the Lebanon mountains and the eastern the Anti Lebanon range. To the west of the Lebanon range is the coastal belt between the ranges is the highly cultivated Buka plain and east of the Anti-Lebanons is the Syrian desert. The Euphrates river passes through the north-eastern parts, the Orontes rises in the Buka and flows north, the Litany also rises in the Buka but flows south and the Barada flows east through Damascus. Many rivers cross the coastal strip, the majority are small, stony streams which dry up in late summer. Coastal swamps exist at the river mouths and there are a number of inland swamps and lakes. Ancient and modern irrigation canals, cisterns, wells, holes and man made depressions are scattered all over the countryside.

The climate of the coastal belt is generally sub-tropical, that of the mountains temperate and that of the Buka extreme. From May to October heat and dryness increase from west to east and little moisture crosses the Anti Lebanon which form a barrier between Syria and the Syrian desert. Wind is generally from the west and south west.

The species of *Anopheles* are 4 *sacharovi*, 4 *superpictus*, 4 *claviger*, 4 *sergenti*, 4 *hyrcanus*, 4 *algeriensis*, 4 *marteni* and 4 *multicolor*. The first seven are established but 4 *multicolor* though common in Palestine has only been taken once north of the border. The first three are important vectors of malaria. Keys are provided for the identification of adults and larvae and a table is given of characters for the separation of the closely allied 4 *claviger*, 4 *algeriensis* and 4 *marteni*. The figures are unfortunately rather indistinctly reproduced.

A. sacharovi is capable of maintaining intense malaria. It breeds in inland and coastal swamps and in springs, cisterns and pools where the water surface is covered with a layer of vegetation. In winter females settle in houses, barns and stables near a food supply from whence they emerge on warm days to feed and then retire to their hiding places. *A. sacharovi* is a strong flier and in the Buka may travel five to ten kilometres aided by the wind.

A. superpictus transmits much of the rural malaria particularly in the coastal belt. Larvae are commonest from May to October in the sunlit parts of mountain streams among stones and boulders, in springs, ditches and irrigation channels. They also occur in water which collects in sand and gravel pits. *A. superpictus* breeding places are flooded out in winter consequently control measures need to be repeated each season. Adults enter houses and stables at night but their flight range is limited, possibly to a maximum of two kilometres.

In towns and villages 4 *claviger* is the important species and breeds in wells though if the spleen rate is over 10 per cent. breeding places of other species may be implicated. Introduction of piped water supplies has sometimes worsened the situation because the disused wells have remained untreated. In rural areas shaded parts of rivers and mountain streams also breed 4 *claviger* which is the first anopheline to appear in springtime.

The transmission of malaria in this region by *A. sergenti* is not confirmed but it must be regarded as a potentially dangerous species. Larvae are sometimes found with those of *A. superpictus* in stream beds, canals and ditches, but not in marshes. Its flight range is not great and it is thought to overwinter as an adult.

The remaining species are unimportant. *A. hyrcanus* and *A. algeriensis* breed in marshes and will bite in sunlight. *A. marleri* breeds in shaded pools in hilly country. *A. multicolor* has not established itself in Syria and Lebanon.

The author suggests that the attack on the three malaria vectors should consist in spraying winter quarters of *A. sacharovi* and *A. superpictus* with 5 per cent DDT in kerosene or 5 per cent DDT emulsion once in December or January, and once in March, followed by treatment (with Paris Green malarial or DDT) of all potential breeding places once a fortnight. In the case of *A. claviger* he suggests that wells and cisterns be sprayed every two months in rural areas. He considers that the *superpictus* control measures will suffice for the *claviger* problem also. He believes that it is possible to devise and execute such an extensive programme and proposes that advice and direction should be sought from those who dealt with the eradication of *A. gambiae* from Brazil and Egypt.

H S Leeson

KALANDADZE L P & SAGATELOVA, I S [Concerning Dry Hardiness of Mosquito Larvae on Dry and Humid Substrata.] *Med Parasit & Parasitic Dis* Moscow 1945 [1946] v 14 No 6 19-25. [In Russian.]

Working with larvae of *Anopheles maculipennis maculipennis*, *A. bifurcatus* [*A. claviger*] and *Culex pipiens* the authors carried out a series of experiments with the view to determining their viability on dry and humid substrata. The striking term dry hardness is used by the authors. Batches of 20 larvae of each age-group were placed in 100 cc crystallizers containing at the bottom a layer of earth, sand, plants chips of wood or a filter. After exposure for different periods of time water was added to the substratum and on the following day a count was made of the percentage of live and dead larvae. In a control crystallizer water was added at the beginning of the experiment. Experiments on humid substrata were carried out with a special apparatus [see this Bulletin 1944 v 41 916.]

The results were as follows—(1) The dry hardness of mosquito larvae is considerably less than that of the eggs. (2) the dry hardness of larvae of stages I and II is less than that of larvae of stages III and IV. (3) larvae of *Culex* are more dry hard than those of *Anopheles*. (4) at lower temperatures of the air the hardness of larvae increases both on dry and humid substrata. (5) the dry hardness of larvae on humid substrata (33 per cent moisture in the soil) is considerably higher than that on perfectly dry substrata. Thus the larvae of *A. bifurcatus* of stages II, III and IV can live from 3 to 7 days on humid substrata at 23-24°C and 50-75 per cent relative humidity whereas on dry soil they survive only up to 35 minutes at 24°C.

C A Hoare

FEDERATED MALAY STATES INSTITUTE FOR MEDICAL RESEARCH. The Anopheles of Malaya. Keys for the Identification of the Females and Larvae of the Anopheles Mosquitoes found in the Malay Peninsula. 48 pp. numerous illustrations. 1945 [Prepared by the Staff of the Entomological Division of the Institute for Medical Research F.M.S.]

This handy little booklet is a practical introduction to the identification of Malayan anophelines. It will be useful both to medical and non medical investigators.

The text is simple and accurate. Detailed descriptions of mosquito anatomy are not included but the important morphological features are clearly indicated in the diagrams. In thirty-seven pages the reader is shown how to recognize mosquitoes how to distinguish culicines from anophelines and the different species of *Anopheles* from one another. Instructions are given for using the keys for the identification of females and larvae of Malayan species. The keys are followed by brief descriptions of eighteen important species notes on their habits distribution breeding places and relation to malaria and a brief glossary of some technical terms.

In the few remaining pages there is a short account of malaria in the Malay peninsula and a description of the man baited double net method of trapping mosquitoes.

DAGGY R H The Biology and Seasonal Cycle of *Anopheles farauti* on Espiritu Santo New Hebrides. *Ann Ent Soc Amer* 1945 v 38 No 1 1-13
(Summary taken from *Rev Applied Entom* Ser B 1946 Aug v 34 Pt 8 122-3)

Anopheles farauti Lav * the mosquito formerly known as *A punctulatus moluccensis* Sw & Sn * occurs in the New Hebrides (including the Banks Islands) the Solomons Bismarck Archipelago Admiralty Islands and eastern New Guinea and is the most important vector of malaria in the Australasian region. It was studied from October 1942 to September 1943 in Espiritu Santo (New Hebrides) where it is the only Anopheline and malaria is hyperendemic. An account is given of the precipitation geological structure and drainage of the island. *A farauti* is primarily a coastal mosquito though the author found it to be abundant at an altitude of 1 100 ft. on Gaua Island in the Banks Group. Permanent breeding places in Espiritu Santo include rivers streams springs taro gardens seepage areas ponds lakes swamps marshes open wells and fresh water and slightly brackish lagoons. During the rainy season breeding occurs also in such temporary sites as pools ruts and hoofprints. The breeding places vary widely in respect to sunlight temperature plant growth turbidity and movement. Breeding and malaria transmission occur throughout the year wherever water is available but in the south-eastern part of the island, where there are few permanent breeding places transmission takes place principally in the rainy season. At this time adults are produced in large numbers in all breeding places except some of the larger rivers from which the larvae are flushed by frequent floods. It is estimated that troops were responsible principally through the construction of roads and the movement of heavy equipment for the formation of 90 per cent of the temporary breeding places in the area in the south-east that has been occupied by them. Moreover the suitability of some permanent water for breeding was increased. The natives favour the transmission of malaria by building villages near rivers and by making water terraces for growing water taro a staple food crop.

The flooding of low lying fresh water marshes with sea water was considered as a possible control measure but investigation showed that the maximum salinity at which breeding can occur is high. Females given a choice of 11 dishes containing water of different salinities varying from rain water to pure sea water oviposited in almost all including the pure sea water though they seemed to have some preference for concentrations of less than 50 per cent. sea water. Eggs hatched in pure sea water but the larvae died in a few hours.

It appears from a recent key that American authorities have concluded that *A farauti* is specifically distinct from *A punctulatus* Dön., and that *moluccensis* H., as is probable it is a distinct form is a sub-species of *farauti* and not of *punctulatus*.

However complete development took place in water containing 13 000 parts chlorides per million (65 per cent. sea water) larvae were found in nature in water containing 13 500 parts chlorides per million (68 per cent. sea water) and larvae taken from such water in the second or third instar completed their development in partly evaporated sea water containing 23 000 parts chlorides per million. Opening low lying areas to sea water may therefore increase the area available for breeding but where tidal flushing is marked and the water is not impounded larvae are greatly reduced in numbers or eliminated.

In individuals reared in the laboratory at 23-30°C [82-86°F] on dog biscuit the egg, larval and pupal stages lasted 1½-2, 10 and 1½ days respectively. The cycle in open sunlit pools is probably shorter. The females attack man readily though they also feed on animals. In houses or tents with artificial light they bite chiefly in shaded corners or on shaded parts of the body. They feed principally but not exclusively at night. Their bite is painless and their flight relatively quiet. They sometimes used artificial shelters such as dwellings, tents, boxes and large tins as diurnal resting places but were also found on the walls of slit trenches and the underside of logs. They were never found, however in standard boxes placed in favourable situations in attempts to estimate adult populations. From observations on the distances between areas in which malaria occurred in the dry season and the nearest breeding places it was estimated that the effective flight-range of the females is ½-1 mile and intensive control measures within this radius considerably reduced the malaria rate. A female was found, together with mosquitos of other species on a boat 600 yards offshore where the crews of several boats were reporting mosquito annoyance at night and becoming infected with malaria.

Filaria with nocturnal periodicity is endemic in the New Hebrides. Of the mosquitos occurring there the only ones in which the complete development of *Filaria (Wuchereria) bancrofti* has been observed are *A. farauti* and *Culex fatigans* Wied. (*quinquefasciatus* auct.) and as the latter is recently introduced and rare *A. farauti* is probably the important vector.

EADS R. B. A New Record of *Anopheles albimanus* in Texas. *J. Econom. Entom.* 1946 June v 39 No 3 420

"Five *Anopheles albimanus* females were taken within a two-week period from three different locations near the Corpus Christi Naval Air Station. This represents the first known migration of this species from the Lower Rio Grande Valley into other parts of Texas.

PACKER H. The Use of Darkfield Illumination in Studies of Malaria Parasites. *J. National Malaria Soc. Tallahassee Fla.* 1945 Dec. v 4 No 4 331-40 5 figs.

In this paper the author gives an account of his experience with the use of dark field illumination for the study of malaria parasites. He describes the apparatus he has found most useful and his method of preparing blood for examination. He advocates the admixture with the blood of a little distilled water or tap water by inserting a small drop of water on the coverglass on to the drop of blood on the slide. Rapid detection of *Plasmodium mraz* was possible owing to the brilliant refractiveness of its pigment which was in active Brownian movement. The method is less satisfactory for *P. falciparum* owing to the paucity of pigment in the young rings which are the forms in the peripheral blood. Observations are readily made on the process of exflagellation. The author concludes that when blood examinations are intended for the discovery of *P. mraz* alone the dark field method is often the most rapid for obtaining a diagnosis.

GUTH, G. S. A Case of Quinine Amblyopia. *Indian Med Gaz* 1946 June-July v 81 Nos. 6-7 238-41 5 charts.

HALAWANI, A. & NOR EL DIN, G. A Case of Raynaud's Disease-like Condition of Unusual Severity following Intramuscular Quinine Injections. *J Roy Egyptian Med Ass* 1946 Jan-Feb v 29 Nos 1/2 84-9 2 figs

1. A case presenting the signs and symptoms of Raynaud's syndrome was described. The patient was a female Mohamedan aged fifteen years from the Dakhla Oasis of the Egyptian Western Desert. She was suffering from chronic malaria and syphilis but there was no haemoglobinuria.

2. The point of interest of this case are the close relation between the administration of quinine in the gluteal muscles and the onset of the lesion the severity of the condition (leading to gangrene with complete loss of the toes) and its occurrence in only one limb and that limb being the lower extremity.

LANGE, K. & MATZNER, M. J. The Distribution of Atabrine in the Blood, the Skin, and its Appendages. Methods for the Rapid and Simple Detection of the Presence of Atabrine in Blood, Skin, and Nails. *J Lab & Clin Med* 1946 July v 31 No 7 742-8 4 figs 10 refs

The authors have used a single extraction method in conjunction with a fluorocomparator to estimate plasma levels of atabrine. The earlier methods described for the estimation of this substance this *Bulletin* 1938 v 33 273 1938 v 36 103 569 lacked sensitivity while the methods of BRODIE and LUDENFRIED and of MASEN this *Bulletin* 1944 v 41 453 1945 v 42 87 which meet all requirements demand considerable skill and laboratory resources. The present method consisted in basifying the plasma and extracting atabrine base with ether. Fluorescence in the extract was then measured by a fluorophotometer or visual fluorocomparator with selective light filters to cut off undesired fluorescence repeated extraction with solvents was thus avoided. The technical details of the instruments are described. By the above means the plasma levels in 22 patients receiving atabrine for treatment of relapsing *P. vivax* infections were studied. The authors found that 0.3-0.6 gm. atabrine on the first day followed by 0.2 gm. daily for 7 days was no sufficient to give a desired plasma level of 100 microgrammes per litre but that this level can be reached in 24 hours if 1.2 gm. is given on the first day followed by 0.6 gm. on the following day and 0.3 gm. daily thereafter during treatment. Use was also made of ultra violet light of wave length 3 600 Angstrom units to excite fluorescence in the skin and appendages of atabrine treated patients which could be observed visually or measured quantitatively by a photoelectric Dermofluorometer previously described. No direct correlation was found between the amounts of atabrine present in plasma and skin. Observation of the fluorescence in nails readily indicated whether atabrine was being taken regularly. J. D. Fulton

SMITH, L. H. & STOECKLE, J. D. Effect of Quinaerine Hydrochloride (Atabrine) on Isolated Mammalian Heart. *Proc Soc Exper Biol & Med* 1946 June v 62, No 2 179-84 2 figs [13 refs]

A study was made of the effect of adding mepacrine to the heart lung preparation of dogs. Contractility of the heart muscle was impaired, so that the output of the heart diminished and the volume of the heart increased. The outflow from the coronary sinus did not change significantly. Bradycardia occurred sometimes but not always. The electrocardiograph was approximately normal. These changes could be reversed by adding cardiac glucosides.

(ouabain or K-strophosid) The minimal toxic concentration of mepacrine was about 1 mgm. per litre of whole blood 1.5 mgm. per litre was regularly toxic Much of the mepacrine was rapidly removed from the circulating blood 50 per cent disappeared from the blood in 15 minutes in one experiment in another 90 per cent disappeared in about 50 minutes although the heart and lungs are the only tissues available in the preparation to take it up Rapid injection of mepacrine leads to severe heart failure but a slow infusion of the same amount can readily be tolerated Accordingly if mepacrine is to be given intravenously it should be given extremely slowly *F Hawking*

GUTIERREZ SÁNCHEZ Elena Acumulación y excreción de la atebriina en el ratón [Concentration and Excretion of Atebrin in Mice.] *Rev. Inst. Salubridad y Enfermedades Trop.* Mexico 1946 Mar v 7 No 1 1-12, 1 graph 14 refs Summary in English by the author

A study was made of the concentration of atabrine chlorate, *sic* in the original it is Clorhidrato in the blood of white mice its excretion in the faeces and urine and its storage in the liver spleen lungs heart intestine and kidneys. The drug was administered orally 113 mgs per kilogram of weight 24 mgs. intravenously and 25 mgs intraperitoneally in a single dose and repeated doses

"The atabrine concentration in the blood with one daily dose for several days never exceeded 0.50 mgs per cent but this low concentration continued for five days after treatment was suspended.

High concentrations of the drug were found in the liver disappearing completely eight days after the treatment was suspended Lower concentrations were found in the spleen and lungs

KAPLAN, L I READ, H S & BECKER, F T The Action of Thiobismol on Therapeutic Quartan Malaria. *J Lab & Clin Med* 1946 July v 31 No 7 733-41 1 fig

It was shown by SCHWARTZ (*J Pharm. & Exper Therap* 1939 v 65 175) that sodium bismuth thioglycollate (thiobismol BI (SCH_2COONa)₂ had some effect in controlling the number of paroxysms during therapeutic malaria treatment with *P. malar* YOUNG *et al* this *Bulletin* 1943 v 40 881] failed to obtain consistent results with *P. malariae* and the drug was apparently without action on *P. falciparum* Investigation has now been made with this drug in 38 patients with blood induced *P. malariae* infections who were experiencing true quartan double quartan or quotidian attacks in order to find out at what stage of growth the parasites are affected and also its effect on the paroxysms. Fifty-six injections of the drug in 0.1 or 0.2 gm doses were given intramuscularly at irregular intervals. Its controlling effect on the paroxysms was decided by relating the time of administration to the growth stage of the parasite in all types of cycle encountered. Young or mature forms of the parasite were

practically unaffected. In about half the patients with true quartan cycles the drug exerted a definite clinical effect because of its action on immature forms of the parasite. Paroxysms were interrupted in a very large percentage of patients experiencing the other types of cycle and the partially mature forms of the parasite were chiefly affected. Patients with parasite counts above 10 000 per cmm. showed no clinical response to treatment but the parasite numbers were reduced. The authors conclude that in quartan malaria the drug is of value in reducing the frequency of paroxysms and in controlling irregular cycles. It should aid neurosyphilitics undergoing treatment to tolerate better a full course of therapy with this parasite.

CLUVER F W P Report on Malaria Control in Rural Native Areas by using D.D.T Insecticide. *South African Med J* 1946 July 13 & 20 No 13 368-70

The author working in a Zululand Reserve reports on the substitution of weekly insecticidal spraying of native huts with Pyagra paraffin by the alternative method of 5 per cent DDT in commercial paraffin. The local anopheline vectors of malaria are *Anopheles gambiae* and *A. funestus*. The results in an admittedly small scale experiment illustrate the inefficiency of a weekly pyrethrum spraying programme when compared with the degree of adult mosquito eradication attained with DDT.

Park Ross instituted insecticidal spraying in Zululand this *Bulletin* 1937 & 34 581 with resultant control of seasonal epidemic malaria. It remains to be seen what effect the general use of residual DDT as described by the author will have on endemic malaria.

The author quotes a saving of 12 per cent in costs in the replacement of weekly Pyagra by three-monthly residual DDT. The additional benefit of a heavy fly and cockroach mortality is noted.

R Ford Tredre

JOHNSON H. A & EASON J L. Jr DDT in Paradichlorobenzene as a Larvicide. *Pub Health Rep* Wash. 1946 Aug 9 & 61 No 32, 1185-8 1 fig

DDT pellets were prepared by melting paradichlorobenzene and adding solvents containing DDT and emulsifiers and DDT in crystalline form. Details of two of the seven formulae are given here as examples —

- { 475 cc. paradichlorobenzene
- 25 cc. of a 50% solution of DDT in Velsicol 70 plus 1 5% Triton X 100
- 20 gm. DDT
- { 475 cc. paradichlorobenzene
- 25 cc. of a 7% solution of DDT in No 10 motor oil.
- 20 gm DDT

Suspension of the pellets in water in field experiments resulted in slow disintegration 50 per cent of volume in 14 weeks. A marked reduction in mosquito larvae occurred for the first six weeks after which scum and vegetation began to interfere with the action of the DDT. The authors consider the results attained were promising and that a higher rate of pellet disintegration would result in a higher degree of *Anopheles* control.

KRUSE C W & METCALF R. L. An Analysis of the Design and Performance of Airplane Exhaust Generators for the Production of DDT Aerosols for the Control of *Anopheles quadrimaculatus*. *Pub Health Rep* Wash. 1946 Aug 9 & 61 No 32 1171-84 5 figs.

The authors describe a method of control from the air by DDT larvicide of the larvae of *A. quadrimaculatus* under conditions encountered on the unpounded

waters of the Tennessee Valley Authority. Spraying of such areas is attained by the atomization of a DDT solution by the exhaust gases of the airplane engine. The larvicide is injected into a venturi extension of the engine-exhaust by a wind-driven pumping unit. The following desirable factors in a DDT solvent for this use are quoted —

(1) High solvent power to permit the use of concentrated solutions which greatly increase payload
(2) low volatility which increases safety factors this is desirable for the persistence of the solution on the water surface and decreases evaporation of solvent due to the hot exhaust gases and
(3) non-corrosive and non-poisonous chemical properties.

The methylated naphthalenes were chosen, and in particular a fraction Velsicol NR 70 (Velsicol Corporation Chicago) was readily available a 20 per cent solution of DDT in the latter solvent was used.

The optimum size of aerosol droplet deposited on water surface lay between 25 and 50 microns in mass median diameter this particle size (35 microns) enabled 200-foot swath widths from a height of 30 feet to receive the adequate larvicidal dose of DDT a particle size of under 60 microns ensures adequate penetration of heavy vegetation cover. A deposit of 0.0001 lb. DDT per acre (1 microgramme of DDT per square foot) with a 35-micron particle size killed 90 per cent of 4 *quadrimaculatus* larvae in the open. In practical application the authors recommend the following deposit figures per acre to ensure a 90 per cent *A. quadrimaculatus* larval kill — Open 0.0005 lb DDT medium cover 0.0025 lb DDT high cover 0.005 lb DDT. A table is given showing the widths of 90 per cent larval kill which will be obtained under varying rates of plant cover aerosol discharge and flight pattern.

[This paper is a valuable contribution on this method of anopheline control.]

BEKLEMISHEV V N, SHLEKOVA, M F & ORLOV P M. [Experiment on the Determination of the Necessary and Sufficient Radius of Antilarval Treatment.] *Med Parasit & Parasitic Dis* Moscow 1945 [1948], v 14 No 6 3-8 fig. [In Russian]

A knowledge of the size of the area to be covered in undertaking anti-larval measures for the protection of a given site against malaria is of great practical importance. If the radius is too small mosquitoes continue to enter the protected zone. If it is excessive considerable unproductive expense is involved. In general, the area of the protected zone is proportional to the square of its radius. The actual practice varies according to local conditions. In the case of *Anopheles maculipennis* a width of 3 km. is considered to be sufficient but in the tropics it is usually reduced to 1-6 km. while in Russia it is sometimes extended to 5 km.

Working in the flood area of the Volga, near Kuibyshev in 1940 and 1941 the authors carried out experimental field observations on this question. The problem was to determine the effect of the width of a controlled zone surrounding a settlement, which it was desired to protect upon the influx of mosquitoes into the settlement in other words to ascertain the rôle of each concentric belt around the settlement upon the mosquito density in it. With this end in view an estimate was made of the density of larvae in an area with a radius of 3 km. from the settlement after which complete anti-larval measures were undertaken in all the breeding places within three concentric zones, each 1 km. wide in succession. Originally the zones with a radius of 1 and 2 km. were found to have a uniform density of larval population while in the outer zone (radius 3 km.) the density was much lower. After the first kilometre zone

had been dealt with the larval density within the second kilometre zone was doubled whereas in the third kilometre zone it increased only after treatment of the second zone. This centrifugal increase was probably due to dispersion of female mosquitoes from the water-collections treated with petroleum. While the increased density of the second zone following treatment of the first zone almost compensated for the depopulation of the latter the density in the third zone was unable to keep pace with the losses caused by anti-larval treatment of the first two zones.

The results of these operations were correlated with an estimate of the density of adult mosquitoes within the settlement based on counts made in three control sites. After treatment of the first zone the mosquito density in the settlement was reduced by 82.4 per cent. After treatment of the second zone it fell to 0.3-0.4 per cent of the original density. Thus thorough larval destruction within a radius of 2 km. almost completely stopped the influx of active females (*A. maculipennis messeae*) into the protected settlement. From this experiment it would seem that the clearance of a zone within 2 km. from the protected area was sufficient. However it is pointed out that in this instance the mosquitoes might have been deflected by two other villages within the area of operations and by cattle in the vicinity. It is concluded that whereas in individual cases anti-larval measures might be limited to a radius of 2 km. in other cases it is advisable to cover 3 km. C. A. Hoare

KNISELY M. H. STRATMAN THOMAS W. A. ELIOT T. S. & BLOCH E. H.
Knowlesi Malaria in Monkeys. I. Microscopic Pathological Circulatory
Physiology of Rhesus Monkeys during Acute *Plasmodium knowlesi* Malaria.
A Motion Picture. J. National Malaria Soc. Tallahassee Fla. 1943
Dec. v. 4 No. 4 285-300 [Numerous refs.]

In previous papers this *Bulletin* 1943 v. 40 584] the authors have described the results of investigations carried out by a special technique on the behaviour of blood and the blood vessels in living *Macacus rhesus*. The observations were made on normal monkeys and on monkeys suffering from *P. knowlesi* infection. The results throw light not only on the pathology of malaria but also on the normal physiology of the blood and blood cells. To render these findings available to students and others interested in the subject the authors have prepared a film. It is a 16-millimetre silent Kodachrome picture about 1,500 feet long on four reels and takes from sixty to eighty minutes to project. It was taken through the microscope at magnifications of 32, 48 or 96 diameters. It shows the normal physiology of the blood and the changes which occur when there is a malarial infection leading to the formation of clumps of infected cells which not only impede the circulation but also lead to a condition of anoxia. Finally the effect of atabrin in disintegrating the clumps is shown. The paper describes the film in considerable detail and points out that it is available on loan to medical schools, medical societies, medical officers of the military services and research groups. Applications should be made to Dr M. H. KNISELY, Department of Anatomy, University of Chicago or to Dr T. S. ELIOT, Department of Anatomy, University of Tennessee, Memphis. C. M. Henyon

EXEMPLARSKAYA E. V. [Therapeutic Effect of the Cytotoxic Antitreticular Serum in Malaria of Monkeys (*Macacus rhesus*)] *Ved. Parazit. & Parazit. Dis.* Moscow 1945 [1946] v. 14 No. 6 34-7 [17 refs.] [In Russian.]

In recent years the Russian physiologist BOGOMOLETZ has developed a method of stimulating the defence phagocytic functions of the reticulo-endothelial system with the help of a so-called 'cytotoxic antitreticular serum'

which is produced by immunizing an animal with emulsion of RE tissue of another see *Bulletin of Hygiene* 1944 v 19 823].

In view of the predominant part played by phagocytosis in the defence mechanism of the host in malaria the author tested the therapeutic effect of cytotoxic serum in monkey malaria. The experiments were carried out in *Macacus rhinus* *Macaca mulatta* infected with *Plasmodium inui* while the cytotoxic serum was produced in rabbits immunized with an emulsion of spleen and brain from monkeys (homologous antigen) and from dogs (heterologous antigen). The titre of the cytotoxic serum of rabbits was determined by the complement fixation test and the serum was considered to be suitable at a titre not lower than 1:100. It was injected into the experimental monkeys intravenously in doses of 0.05, 0.1 and 0.2 cc. before simultaneously with, and after induction of infection. Control monkeys either received normal heterologous serum or were infected without any serum. The therapeutic effect of the cytotoxic serum was determined on the basis of the following indications: (1) intensity of parasitaemia and severity of clinical symptoms; (2) temperature reaction; (3) stimulation of activity of reticulo-endothelial cells; (4) haematological picture; and (5) relapses.

The parasite rate was based on a count per 1,000 red cells. The most severe form of malaria, both clinically and parasitologically (8 per cent infected red cells) occurred in monkeys which received the maximum dose of serum (0.2 cc.). It was milder in those which received 0.1 cc. of homologous serum (parasite rate 2.8 per cent) while those injected with the minimum dose (0.05 cc.) had a very mild abortive infection with a parasite rate below 1.5 per cent. The heterologous cytotoxic serum had a relatively slight effect upon the reduction of parasitaemia. Among the control monkeys in those given 0.05 cc. of heterologous serum the course of the disease was as severe as in those without serum while only a slight reduction of parasitaemia occurred in those which had 0.1 and 0.2 cc. serum.

The blood picture as well as the clinical symptoms corresponded to the severity of the disease. The effect of the serum treatment upon relapses was similar to that upon the parasite rate i.e. the higher the dose the greater the liability to relapse, no relapses having been observed in monkeys treated with the minimum dose of serum (0.05 cc.).

It is concluded that treatment with cytotoxic antireticular serum leads to a stimulation of the defence phagocytic function of the reticulo-endothelial system in infected monkeys which results in a suppression of all manifestations of the infection, the maximum effect being produced by the lowest doses of the serum.

HAAS V. H. WILCOX Aimee & EWING Frances M. Infection of Chick Embryos with Non-Pigmented Forms of *Plasmodium gallinaceum*. *J. National Malaria Soc.* Tallahassee Fla. 1945 Dec., v 4 No 4 279-84

The authors show that inoculation of an emulsion of brain substance containing exoerythrocytic stages of *P. gallinaceum* into the yolk sac of developing chick embryos leads to infections which are chiefly of exoerythrocytic forms. Erythrocytic forms are either absent or few in number. It has also been shown that subinoculation with emulsions of the brains of infected embryos leads to the same type of infection. Seven serial passages have been made in this way so that it would seem that a preponderating exoerythrocytic infection could be carried on indefinitely. In a certain number of chicks which hatched and were found to be infected, the infection was of the same type. As regards the erythrocytic forms in the embryos it was noteworthy that many of these were without pigment. It is thought that these pigmentless forms are directly

developed from merozoites of exoerythrocytic forms. As chicks inoculated with blood of embryos containing pigmentless erythrocytic forms develop infections of the ordinary type in which the erythrocytic forms contain pigment it is assumed that in the embryos or in the chicks found infected when hatched the pigmentless forms would have acquired the power of forming pigment had the hosts lived long enough for several cycles to have occurred. *C M Wenyon*

HUFF C G & COLLSTON F The Relation of Natural and Acquired Immunity of various Avian Hosts to the Cryptozoites and Metacryptozoites of *Plasmodium gallinaceum* and *Plasmodium relictum* *J Infect Dis* 1946 Mar-Apr v 78 No 2 99-117 3 figs [25 refs.]

When chickens are infected with *P. gallinaceum* by blood inoculation after an incubation period the length of which depends on the dose of infected cells administered there develops an infection the intensity of which varies with the size of the inoculum. Exoerythrocytic forms begin to appear at about the eighth day and they reach a maximum at about the 25th day. The chickens may die at this stage though very few or no erythrocytic parasites are present in the blood following the falling off of the blood infection at the crisis. A relapse of the blood infection of short duration may occur and if the bird survives the exoerythrocytic stages are rapidly reduced. When sporozoites are injected instead of blood blood infections result whose intensity varies with the dose. When the dose of sporozoites is small the resulting blood infection may be difficult to detect. In any case there is an incubation or prepatent period which varies little (5 to 8 days). Following the injection of sporozoites pre-erythrocytic stages are very abundant in the tissues. When canaries are inoculated with blood or with sporozoites no blood infection occurs and exoerythrocytic stages cannot be found in the tissues. The canary is therefore completely immune to *P. gallinaceum* infection.

Ducks and geese occupy an intermediate position. Blood inoculation produces a transient blood infection but no exoerythrocytic stages can be found. When sporozoites were injected, geese showed a transient parasitaemia but the presence of parasites in the blood of the duck was demonstrable only by inoculation of 1-5 cc of blood into chicks. In ducks following blood or sporozoite inoculations parasites might persist in the blood as proved by chick inoculations for as long as 8 months. No exoerythrocytic stages could be found in the tissues. Some experiments carried out with guinea fowl showed that those birds behaved in the same way as the ducks. These observations showed that ducks geese and guinea fowl occupied an intermediate position between chickens and canaries as regards susceptibility to *P. gallinaceum*.

It was of interest to discover whether this relative immunity of these birds had any influence on the development of sporozoites. When sporozoites are injected into the skin of the wing of chickens their development into cryptozoites and metacryptozoites (pre-erythrocytic stages) can readily be followed at the site of inoculation. When this is carried out in ducks and geese the complete development takes place as in chickens. In canaries as noted above no such development occurs. It seems clear that the natural immunity of the duck and goose which influences the blood infection has no effect on the development of the pre-erythrocytic stages. Attempts were made to render three ducks more susceptible by inoculating them repeatedly with chicken's blood before injecting sporozoites. In two parasites were seen in the blood in small numbers during three days. In some cases at least these parasites appeared to be in chicken erythrocytes. Conversely attempts to reduce the susceptibility of chickens by inoculations of ducks' blood were not very convincing. When inoculated with sporozoites the chickens developed modified blood infections—an observation

TRYPANOSOMIASIS

WILHE J K H & FRENCH M H. An Experimental Study of Trypanosoma rhodesiense Infection in Zebu Cattle. } Comp Path & Therap 1945
 July v 55 No 3 206-28 12 charts [18 refs]

Six zebu oxen were used in the experiment they had been living for several months in an area which was concluded to be free from tsetse flies and tests made before the experiment began indicated that they had no trypanosome infection.

The Kahama strain of *Trypanosoma rhodesiense* [this Bulletin 1936 v 33 651] in the blood of heavily infected white rats was injected subcutaneously into the six oxen and all showed trypanosomes in their blood after 7 to 13 days. The trypanosomes appeared irregularly they were polymorphic mostly long forms, and later only on occasional days they were polymorphic mostly long forms, and no posterior nuclear forms were seen.

The red and white blood corpuscles showed no variations in number that could be attributed to the infection and the haemoglobin content never fell below 82 per cent which is not abnormal in zebu cattle during the dry season when this experiment was made. The red cell sedimentation rate showed little change.

Plasma proteins—These were estimated periodically throughout the experiment which lasted for about 6 months. The proteins were fractionated with sodium sulphate by HOWE'S technique (J Biol Chem 1931 v 49 93 & 109) and nitrogen determinations were made with the micro-Kjeldahl method. The variations in total protein non-protein nitrogen and pseudoglobulin were small and irregular and no appreciable change occurred in the fibrinogen the eglobulin increased rapidly reached maximum levels between the 6th and 15th days after inoculation and then steadily decreased but had not reached normal levels after 20½ weeks. The albumin decreased rapidly and reached the lowest levels when the eglobulin was at the maximum. The authors conclude from these findings that infection with *T. rhodesiense* either (a) caused an increase in the dimensional proportions of the plasma protein molecules or (b) altered the conditions of the plasma so that larger proportions of its proteins were precipitated at lower electrolyte concentrations. These changes could not be compared with those in *T. brucei* infections of oxen owing to lack of data of the latter.

The blood sugar was determined by the method of HAGEDORN and JENSEN (Ugeskr f Læger Copenhagen 1918 v 80 1117) no hypoglycaemia was observed.

Clinical symptoms were slight soon after infection the temperature showed certain fluctuations and some of the oxen had transient malaise but they did not lose weight and never gave the impression of being fly-struck.

Pathology—Six months after the oxen were inoculated, 20 cc of the blood of each was injected on two successive days into a goat. Three of the six goats (from oxen Nos 33 34 and 35 respectively) showed infection. Two oxen (35 and 36) were then stunned and slaughtered and examined microscopically. Sections being prepared from many organs were found. Guinea pigs were inoculated with cerebrospinal fluid of ox No 36 (the stunning produced cerebral haemorrhage in ox No 35) and did not become infected.

The authors conclude that *T. rhodesiense* is only mildly pathogenic to zebu cattle, but that it is reasonable to assume that during at least the first six months of *T. rhodesiense* infection, cattle can act as true carriers of the disease and so are a source of danger to humans when moving from areas where sleeping sickness is endemic to other tsetse fly-infected areas from which

T. rhodesiense is absent [An attempt to infect volunteers from the cattle would have been interesting there is of course now no reasonable doubt that wild and domestic animals are reservoirs of *T. rhodesiense* and their importance as such in various areas needs investigation.]
J F Corson

BURTT E Observations on an Antbear (*Orycteropus afer*) in relation to Infection with *Trypanosoma rhodesiense* Trans Roy Soc Trop Med & Hyg 1946 June v 39 No. 6 529-32

The author discusses his own observations on experimental infection of an antbear with *Trypanosoma rhodesiense* and compares them with those of VANDERPLANK [see this Bulletin 1941 v 38 632] who suggested that the lower the normal temperature of this host before infection (in his case 97°F) the higher was the subsequent transmissibility of the trypanosomes in tsetse flies (in his case 2 per cent had salivary gland infections) and the shorter was the life of rats infected by flies i.e. the greater was the virulence of the trypanosomes (his rats lived on the average 18 days) Burtt points out that though Vanderplank's suggestion is borne out by the short duration of the infection in rats it is not supported by the low transmissibility in the flies. In the experiments conducted by Burtt the temperature of the antbear was 95°F the percentage of flies having salivary gland infections was 1.5 while the average duration of life of rats infected by the flies was 40.5 days. These results agree with those of Vanderplank as regards the low infection rate in the flies but they do not support his contention that transmissibility and virulence of *T. rhodesiense* may be increased by passage through hosts with a low mean body temperature.

C A Hoare

FULTON J D & STEVENS T S The Glucose Metabolism *in vitro* of *Trypanosoma rhodesiense* Biochem J 1945 v 39 No 4 317-20 [23 refs.]

The authors have studied the glucose metabolism of *Trypanosoma rhodesiense* maintained in a medium containing a small amount of serum. Some tests were conducted in a serum-free medium but the trypanosomes did not survive so well with the result that the yield of metabolic products was low. The products isolated were succinic, pyruvic, lactic, acetic and formic acids, glycerol, ethanol and carbon dioxide. The method of detection of these products is described and the possible paths of their production and the results of earlier work on trypanosome metabolism, are discussed.

C M Wenyon

BURTT E Salivation by *Glossina morsitans* on to Glass Slides a Technique for Isolating Infected Flies. Ann Trop Med & Parasit 1946 July v 40 No 2 141-4 10 figs. on 2 pls.

The author has developed a discovery originally made by BRUCE that tsetse can be made to salivate on a cover slip. If the fly has a salivary infection the trypanosomes are deposited and may be stained and studied. The chance of finding them is increased if the cover slip is smeared with egg albumin.

Burtt finds that the method is a relatively quick and simple way of identifying those individual flies with a salivary infection of *T. rhodesiense*. The method, if repeated on several days, reveals infections which are missed if each fly is fed on a separate rat (which must then be isolated and observed over a period, a laborious method).

Burtt has observed bacteria in saliva, in a very small proportion of flies. The bacteria (which are of several morphological types) may occur in the presence or absence of trypanosomes, though significantly more frequent in their presence. The bacterial infection in the fly is persistent but apparently harmless.

P A Burton

CHABEUR M & MBAPPE J Les grands suspects de trypanosomiase dans les environs d'Ebolowa (Cameroun) [Suspected Sleeping Sickness Cases in the Region of Ebolowa, French Cameroons.] Bull. Soc. Path. Exot. 1946 v 39 Nos 5/6 188-93

Sleeping sickness does not occur in the Ebolowa subdivision to the same extent as in other parts of the French Cameroons although it has been of serious consequence for the past 20 years in the Nyong Valley only 100 km. away. In 1942 no more than 212 persons were found to be infected among 45 000 examined in the subdivision and three peculiarities were noted at that time — (1) the occurrence of cases clinically resembling sleeping sickness but in which trypanosomes could not be found in the blood, gland juice or c.s.f. (2) extreme paucity of tsetse fly and (3) the high proportion of cases whose infections were acquired in other regions.

It is not uncommon to find patients whose c.s.f. is grossly abnormal and the question repeatedly arises whether such cases in which the patients are suspected of suffering from sleeping sickness, are not in fact cases of syphilis. In order to investigate this problem the authors decided to keep under observation in the Ebolowa Hospital for one year 28 patients suffering from chronic nervous (and in most cases mental) disturbances. Only two of these patients came from outside the region.

Examination of the blood, even after provocative injection of sodium thio-sulphate or other substances consistently failed to reveal trypanosomes, except in one patient who had been ill for three years and whose c.s.f. was grossly pathological. Bone marrow examinations revealed no trypanosomes in any case.

In 18 of the patients the cell-count and albumin-content of the c.s.f. were markedly increased, but this picture improved (though only for a month or two) after trypanamide in the 13 cases so treated. The authors consider this (with doubtful justification) to be strongly suggestive of sleeping sickness as the correct diagnosis.

The Verne reaction which is ordinarily negative in trypanosomiasis uncom-plicated by syphilis was positive in only three out of eight cases suspected of being syphilitic.

The most interesting clinical feature of the entire group was the frequency of hemiplegias. This was the presenting condition in 12 of the cases. It was of sudden onset together with fever and headache and tended to improve in most cases without any treatment but leaving the patient after several months with characteristic residual impairments of movement, speech, and ideation. The other clinical signs and symptoms of these and the remaining cases are fully described, and the authors conclude that the variety of signs, and the impossibility of systematizing them, can only lead to the conclusion that they represent more or less intense and irreversible disseminated lesions attributable to a trypanosomal encephalitis possibly due to the well-known diffuse perivascular infiltration of sleeping sickness.

Nearly all the cases which most strongly suggested nervous trypanosomiasis responded rapidly to trypanamide but relapses were frequent and some such patients died, to all appearances as cases of sleeping sickness. In the absence of specific treatment the patients progressively deteriorated. In the absence of the c.s.f. was normal or nearly normal, were especially refractory to treatment, and anti syphilitic treatment hardly ever gave encouraging results.

The authors feel justified in diagnosing sleeping sickness in most of these cases, on general clinical grounds, as well as by a process of exclusion of other diseases. The epidemiological peculiarity is that in a region free from endemic sleeping sickness there are always to be found a small number of cases

of this disease in which trypanosomes cannot be seen. Where when and how did these persons become infected? The authors discuss various possibilities without reaching any definite conclusions.

The clinical differentiation between trypanosomiasis and syphilis is not always as clear-cut as is often supposed. The fact that classical tabes and G P I are still unknown in the area under review does not mean that central nervous system syphilis does not occur. Syphilitic myelitis cerebral arteritis and meningitis undoubtedly do occur though rarely and four of the present series were found to be syphilitic. The diagnosis of syphilis is however often reached too hastily. If one carries out serological tests among indigenous patients formerly given insufficient treatment on a diagnosis of syphilis one rarely finds unequivocal positive reactions coinciding with nervous troubles characteristic of that disease.

The authors discuss other possible causes of the conditions they have observed. They write that the neurotropism of tropical infectious diseases is as yet insufficiently explored and they admit that their own incursion into the subject is to present rather than to solve a problem which remains for further investigation.

FULTON J D & HARRISON C V. An Outbreak of *Trypanosoma cruzi* Infection in Indian Monkeys. *Trans Roy Soc Trop Med & Hyg* 1946 June v 39 No 6 513-20 6 figs on 1 pl. [11 refs]

The authors report the occurrence in Liverpool of infection with *Trypanosoma cruzi* in six macaque monkeys out of a batch of ten recently imported from India and in two others which had been in the laboratory for two years. The trypanosome had all the morphological developmental and cultural characters of *T. cruzi* which are described in detail. In connexion with experimental work carried out on these monkeys it was possible that in some cases the infection was transmitted from one monkey to another by blood inoculation. In discussing the possible source of these laboratory infections the authors note —(1) that the ship in which the monkeys had been transported called at a number of ports in South America and passed through the Panama Canal i.e. they had been in the endemic areas of Chagas's disease (2) that a strain of

T. cruzi in mice is kept in the same building and (3) that bed-bugs were also discovered there but none was found in the monkey cages and those examined for flagellates were negative. Infection with *T. cruzi* had already been reported from Asiatic monkeys kept in European and North American laboratories on several previous occasions.

To account for such laboratory infections some observers have suggested that the distribution of *T. cruzi* is not restricted to the New World, and that the infections in the monkeys had been naturally acquired by them in Asia. The present authors leave open the question regarding the source of infection in their monkeys but do not exclude the possibility of a laboratory infection acquired in Britain.

[Though the fact is not mentioned in the present paper the reviewer is aware that in at least two of the laboratories to which the authors refer strains of *T. cruzi* are maintained in rodents while in one of them a search carried out after the discovery of *T. cruzi* infection in monkeys revealed the presence of bed-bugs in the animal house. Thus in all these cases of laboratory infection in monkeys the epidemiological factors for the transmission of the infection from the rodents to the monkeys seem to have been present.] The authors conclude that the possibility of *T. cruzi* infection should be borne in mind when working with rhesus monkeys. [This warning might be extended by pointing to the potential danger of the infection being transmitted to human beings by bed bugs under similar conditions.]

FRIEDHEIM E. A. H. & BRESMAN Rose L. An Organic Antimony Compound with Curative and Prophylactic Activity in Experimental Trypanosomiasis. *Proc Soc Exper Biol & Med* 1946 June v 62, No 2, 131-2.

Two types of compound both metal-free are known to have a prophylactic effect in trypanosomiasis: (i) the polysulphonated ureide Suramin (Bayer 205 Antypol etc.) and (ii) amidines such as Pentamidine and Stilbamidine. A third type a quinquivalent antimonial is now described. It is a polymerized sodium salt derived from β -(2,4-diamino-1,3,5-triazinyl-6) aminophenylstibonic acid (synonym: melaminylphenylstibonic acid).

In mice this water soluble compound is tolerated at a single intraperitoneal dose of 2.5 gm./kgm. and *T. equiperdum* infections are cured by 0.0125 gm./kgm. the therapeutic index therefore being 200.

Two experiments are described to illustrate the prophylactic property of the compound. Five mice were treated intraperitoneally by 0.05 gm./kgm. (i.e. 1/50th of the 100 per cent tolerated dose) and were inoculated 69 days later with *T. equiperdum*. They all remained uninfected. The mechanism of this prophylactic action seems to be based on the fact that the drug is resorbed and eliminated so slowly that a sufficient trypanocidal concentration is maintained in the organism over a considerable length of time. This theory is substantiated by the fact that the pK of the compound is such that the free stibonic acid is precipitated by CO_2 from solutions of its sodium salt, and after intraperitoneal and intramuscular injections of the salt a white deposit of the free acid can be readily seen for many weeks on the surface of the peritoneum and between the muscle fibres.

The second experiment illustrates prophylaxis against repeated inoculation. A single intraperitoneal injection of 0.3 gm./kgm. was administered to 105 mice. One month later they were inoculated with *T. equiperdum*. None became infected. The test inoculation was then repeated at weekly intervals. All the mice remained free of infection for 50 days from the start of the experiment but infections began to appear thereafter so that by the 100th day about half and by the 164th day all the mice had exhibited the infection. When this did

eventually arise it differed basically from the classical fulminating septicæmic type and was of a chronic nature such as occurs in man and rabbits with parasites appearing and vanishing from the blood at irregular intervals. In this experiment the mechanism of prophylaxis possibly included an immunological factor

E M Lourie

MAYER R. L. & BROUSSEAU Dorothy Development of Immunity to Reinfection during Chemoprophylaxis of Trypanosomiasis with a New Antimony Derivative *Proc Soc Exper Biol & Med* 1946 June v 62 No 2 238-40

The authors have confirmed the claim of FRIEDHEIM and BERMAN [above] that mice treated with a new antimonial, *p*-(2,4-diamino-1,3,5-triazinyl-6) aminophenylstibonic acid, are protected from infection by *T. equiperdum* repeatedly inoculated over long periods.

Mice treated by a single dose of 0.05 gm./kgm. [route not stated] and subsequently inoculated and reinoculated up to 45 times with *T. equiperdum* remained uninfected for periods up to 330 days but did eventually become susceptible to infection. Such protection lasting two months or more also arose after oral administration of 0.025 or 0.050 gm./kgm. on five successive days.

Two series of experiments as follows were performed in order to show the possible rôle of immunological processes in the protection produced by these means —

1. Normal uninfected mice were treated subcutaneously by 0.05 gm./kgm. Three weeks later serum obtained from these animals was pooled and injected into normal mice which were then inoculated with trypanosomes. Typical fatal infections resulted. The experiment was repeated in exactly the same way except that the initially drug treated mice had been infected with trypanosomes 48 hours previously. Contrary to the experience with the other experiment the serum obtained three weeks later from these mice was found to protect a further series of mice from infection. Other such experiments showed that the anti trypanocidal [sic] effect was obtained five days after the treatment of infected mice. These experiments show that the trypanocidal power of the serum of infected mice treated by the antimonial is not necessarily due to the drug persisting in the body but possibly to other probably immunological processes. Similar results are obtained by the use of neoarsphenamine instead of the antimonial.

2. The development of this property of the mouse-blood is probably an effect of successful treatment and subsequent death of the parasites as has been shown by much other previously published work. In support of this the authors found that mice inoculated with trypanosomes (*T. equiperdum*) which had been killed by repeated freezing and thawing were partially protected against infection the protection being manifested by a protracted incubation period on subsequent inoculation of viable trypanosomes.

LEISHMANIASIS

GHOSH H. GHOSH N. N. & RAY J. C. A Preliminary Note on the Complement-Fixation Reaction in Kala-Azar with a Specific Antigen as an Aid to Diagnosis. *Ann Biochem. & Exper Med* Calcutta. 1945 v 5 No 4 153-8 11 refs.]

The authors report very successful results in diagnosis of kala azar by the complement fixation reaction in which an antigen prepared as follows was used.

Cultures of *L. donovani* on Ray's medium [this Bulletin 1933 v 30 523] were emulsified with 0.25 per cent. phenol in distilled water. The emulsion, matched with No. 8 of Brown's opacity tubes, showed 80 million flagellates per cc. The emulsion was kept for 25 days in a glass phial in the incubator at 37°C. being taken out each day to undergo mechanical shaking for two hours. At the end of the period the contents of the phial were centrifuged, the supernatant fluid, after filtration, being used as the antigen. The test was carried out with slight modification according to Method 4 of the Medical Research Committee's Report on the Wassermann test (1918). It was found to be highly specific being positive in early cases of kala azar when the usual serum tests are still negative.

COLLIER H O J & LOURIE E. M. The Action *in vitro* of Diamidines and other Compounds on *Leishmania donovani*. Ann Trop Med & Parasit 1946 Apr v 40 No 1 88-100 [25 refs.]

The culture medium employed in the tests described was composed of one part of fresh unheated rabbit serum mixed with two parts of a 12.5 per cent. solution of rabbit red blood corpuscles in isotonic saline. The solution was prepared by taking one volume of defibrinated rabbit blood with six volumes of sterile distilled water adding one volume of 6.3 per cent. sodium chloride solution, centrifuging and discarding the deposit. As the highest temperature at which satisfactory growth of *L. donovani* was obtained was 34°C. it was at this temperature that the tests were carried out. A series of tubes of medium containing two-fold dilutions of a drug to be tested were inoculated with flagellates. The tubes were examined on the fifth day and the lowest concentration of drug giving a negative tube was regarded as the effective dose. A total of 40 compounds, mostly aromatic diamidines or closely related substances, were tested. The only ones showing considerable activity were some, but not all, of the diamidines. Antimonials of known activity *in vivo* such as tartar emetic and neostam, were relatively inactive. As regards the diamidines, there was a fair correlation between activity *in vitro* and the reported activity *in vivo*. Compounds with an *in vitro* titre of one million or more had been found to be effective *in vivo*. The *in vitro* technique would appear to be of some value as a screening procedure, at least in this particular chemical group. The leishmanicidal activity of the diamidines has been studied from the point of view of chemical constitution and compared with the similar study of EWING and his colleagues in 1942 on trypanocidal activity [Jl Chem Soc., 1942, 103].

KAMEL, A. Leishmaniasis of Eyelid. 14th Rep Memorial Ophthalmic Laboratory, Giza, Cairo for 1939-1944 124-8.

Cutaneous leishmaniasis is rarely met in ophthalmology; the author describes three cases. The first had a warty growth along the whole length of the left lower eyelid. The second had a small papule in the centre of the left upper eyelid just above the eyelashes which gradually increased in size and ulcerated. The margins became undermined, but not indurated, and the ulcer was not adherent to the tarsus. The third had an ulcer with a granular surface situated on the left side of the nose and cheek. These cases occurred in localities in which the disease has not previously been seen.

Different forms of treatment are mentioned, of which X-ray treatment and diathermy are said to be the best. [No mention is made of intravenous injections of antimony in the general treatment of the disease.]

MÉCHIN R. Quatre nouveaux cas de bouton d'Orient du Tell constantinois traités par la quinacrine locale. [Quinacrine Treatment of Four New Cases of Oriental Sore in the Constantine Region.] *Arch Inst Pasteur d'Algérie* 1946 Mar v 24 No 1 57-9

This is a record of four cases of oriental sore from localities in the neighbourhood of Constantine in Algeria. They are of interest in that they are outside the Sahara area, where the disease is more frequently encountered. The four cases were treated with quinacrine (atebrin) injected into the sores all of which were on the face. For sores not too near the delicate tissues of the eyelids 0.3 gm. of the drug is injected once or twice. For sores on the lids not more than a third of this quantity is injected at one sitting. When the full dose is given healing is rapid cicatrization being complete in three or four weeks. In one case after healing an oedema in the sub-orbital region persisted. This is attributed to the toxic action of the quinacrine on the soft tissues in that neighbourhood.

ANARI M. N. Culture et isolement de *Leishmania tropica*. Leishmanisation prophylactique [Culture of *L. tropica* for Prophylactic Inoculation.] *Arch Inst. d'Hessarek* Teheran 1946 Jan. v 2 No 2 31-5

Working in Teheran the author describes his technique for obtaining cultures of *Leishmania tropica*. With these cultures he has inoculated 120 persons by scarification or intradermally with a view to protecting them against naturally-acquired disfiguring sores on the face. In 90 per cent. of the cases sores developed at the site of inoculation within 20 days to 7 months. As 85 per cent. of the cases of oriental sore are in children in their tenth year it would appear that protective inoculations should be carried out before this age.

LEITÃO J. S. Pónos canina. [Canine Leishmaniasis in Portugal.] *Rev Med Vet* Lisbon 1945 v 40 229-43 English summary. [Summary taken from *Vet. Bull* 1946 July v 16 No 7 218. Signed U. F. RICHARDSON.]

Attention is drawn to the prevalence of canine leishmaniasis in Portugal. In Lisbon it has been estimated that 3-4 per cent. of dogs are infected. As a check on the value of diagnostic methods a full investigation was made of a clinical case of leishmaniasis in a dog from Coimbra. Positive results were obtained by examination of smears of tibial bone marrow and of the contents of cutaneous ulcers and the formol-gel and Takata-Ara reactions were positive. Blood liver skin and ungual matrix smears were negative as were serum flocculation and the neostibosan and formol-neostibosan reactions.

PESSOA, S. B. & BARRETTO M. P. Sobre a localização dos parasitas nos tecidos e a intensidade do parasitismo na leishmaniose tegumentar americana. [Distribution of Parasites and Intensity of Parasitism in S. American Cutaneous Leishmaniasis.] Reprinted from *1 Reunião Anual dos Dermatologistas Brasileiros* Rio de Janeiro 26-28 Sept. 1944 1945 123-36 8 figs on 4 pls. [31 refs.]

The authors discuss the distribution of leishmania in the tissues of patients with S. American cutaneous leishmaniasis and the variations in intensity of the infections. They show that the parasite is nearly always intracellular but may

lie extracellularly between cells which have been separated by oedema resulting from subjacent inflammation. The type of cell most commonly infected is the histocyte but parasites may occur in many other types of cells, including polymuclear leucocytes and fibroblasts. The authors were not able to confirm the statements that parasites may occur in lymphocytes eosinophiles or epithelial cells. As regards the intensity of infections the leishmanias are most numerous in the early lesions which are developing rapidly particularly at the margins of the papule. When ulceration commences parasites may still be numerous before secondary bacterial contamination becomes heavy. In old chronic lesions with intense bacterial invasion it may be difficult or impossible to find them. They also occur in small numbers in the lymphatic glands adjacent to the cutaneous lesions and in the lymphatics leading from them, especially in the nodes which develop along their course. When mucosal lesions appear the parasites are again numerous in the early stages. They become increasingly difficult to find as the lesions become old and when they are secondarily contaminated.

PESSÔA, S. B. & BARRETO, M. P. Sobre as lesões iniciais na leishmaniose tegumentar americana. [The Initial Lesions in S. American Cutaneous Leishmaniasis.] Reprinted from *1 Reunião Anual dos Dermat-Sifilógrafos Brasileiros* Rio de Janeiro 26-28 Sept. 1944. 1945. 27-35. 9 figs. on 3 pls. [22 reis.]

The initial lesion in S. American cutaneous leishmaniasis is shown to be a papule or nodule which may or may not be pruriginous or painful. Not infrequently there is an accompanying adenitis giving rise to a combined primary infection of the skin and glands. In these primary lesions parasites are usually very numerous. The paper is illustrated by a series of photographs showing the primary lesions.

IRIARTE, D. R. Contribución al estudio de la leishmaniosis en Venezuela. [Leishmaniasis in Venezuela.] *Bolet. Laboratorio Clínico Luis Razetti* 1946 June v 6 Nos. 19/20 355-63. 16 figs. [Bibliography.] English summary.

This is an illustrated account of mucocutaneous leishmaniasis in Venezuela with special reference to cases having involvement of the nose, mouth and pharynx. Short histories are given of 13 such cases in patients from 15 to 57 years of age. In the nose the destructive process involves the soft parts and cartilage of the septum leading to depression of the tip of the nose producing a characteristic parrot beak appearance. In the mouth and pharynx the ulceration of the mucosa leads to a thickening of the lips and other affected parts. The chief inconvenience complained of by the patients is nasal obstruction for unlike other conditions involving the nose such as syphilis or tuberculosis there is little or no discharge. As a rule leishmania can be discovered in smears made from the lesions if patient search is made. Thus they were found in all but one of the cases described. When parasites cannot be discovered, the intradermal test of Montenegro is useful in confirming a clinical

diagnosis Treatment has been by intravenous injection of tartar emetic. Certain patients have tolerated daily doses of 0.1 gm. till a total of 2 gm. has been given but actually 0.08 gm. is the highest single dose that can be administered with safety Under this treatment there has been improvement but not complete cicatrization of the mucosal lesions. In connexion with the transmission of the disease five species of *Phlebotomus* are mentioned as possible vectors. In two (*P. longipalpis* and *P. migonei*) previous investigators have recorded leptomonal infections

FEVERS OF THE TYPHUS GROUP

LOWE J Ten Cases of Typhus in Civilians in Calcutta. *Indian Med Gaz.* 1946 Apr-May v 81 Nos 4/5 171-4

The author briefly describes ten cases of fever of the typhus group seen by him in the last quarter of 1945 at the Calcutta School of Tropical Medicine. Only one case had previously been seen at the school—in 1944—although a sharp look-out had been kept since 1942 because of the known occurrence of cases among British and Indian troops stationed in and near Calcutta

The diagnosis was based chiefly on the serum-agglutination reactions according to which four were diagnosed as scrub typhus four as murine typhus one as tick typhus and the remaining case the only one that was fatal as of doubtful type. A petechial rash was seen in two cases No mention is made of any attempt to recover the causative organism.

Eight of the patients had lived in the heart of Calcutta one of these had gone outside the city on fishing excursions another had made a journey to Bombay the rest were not known to have left their homes [but the serological groups to which these or the two patients from rural areas belonged, are not distinguished] No local eschar was seen In two cases there was slight general enlargement of the lymph nodes

No further cases were seen till May 1946 when one patient was admitted for scrub typhus.

John W D McGaw

HABIBI M Etude des lésions anatomo-pathologiques du typhus exanthématique au cours de l'épidémie de 1942-1943 en Iran [Study of the Pathological Anatomy of Exanthematic Typhus in the Epidemic of 1942-1943 in Iran.] *Arch Inst d'Histoire Teheran.* 1946 May No 4 63-75 12 figs. on 2 folding pls [25 refs.]

The opportunity for this study occurred in Iran where in the months January to July 1943 there were 15 500 cases of typhus fever with a fatality rate of 17 to 20 per cent.

The naked-eye and microscopical lesions are clearly described the latter are illustrated by 12 reproductions of photomicrographs. The changes observed were of the usual types.

The author was not satisfied with the results obtained by the Castañeda and other standard methods of staining he recommends prolonged staining (24-48 hours) with Giemsa's stain and differentiation with a mixture of absolute alcohol nine parts and oil of cloves one part.

CODELEONCINI E. Le reazioni di Vidal e Weil Felix nella pratica sull'altopiano Etiopico [The Vidal and Weil-Felix Reactions in the Abyssinian Highlands.] *Boll Soc Ital di Med e Igiena Trop* (Sez. Eritrea) 1945 v 5 Nos. 5/6 71-84 English summary

The author found that serum retained its agglutinating properties much longer when separated from the clot as early as possible.

He points out that serum when exposed to a hot and dry atmosphere without being sealed up may become so concentrated that the agglutination titre is liable to be considerably increased. He found that when dried clot was the only material available this when reconstituted with serum, yielded titres about one tenth as high as the original serum

D IGMATIO C & CODELEONCINI E. La reazione di Weigl nel tifo esantematico. [The Weigl Reaction in Typhus Fever] *Boll Soc Ital di Med e Igiena Trop* (Sez. Eritrea) 1945 v 5 Nos. 5/6 199-210 English summary (6 lines)

The authors carried out 7 500 rickettsia-agglutination tests on the lines originally worked out by WEIGL presumably the rickettsial suspensions were prepared from the guts of infected lice

Between 1938 and 1945 a series of 2 650 Weigl tests were performed simultaneously with Weil-Felix tests 1 640 of these were of sera from 368 cases of louse-borne typhus the rest included sera of typhus convalescents healthy persons (vaccinated and unvaccinated) trachoma patients Abyssinian prisoners and persons employed in the laboratory as donors of blood meals for infected or uninfected lice.

The conclusions reached were that although the Weil Felix test was highly reliable the Weigl test had the advantages of never becoming positive in patients suffering from diseases other than typhus and of yielding a significant response about one day earlier

Apart from the earlier rise and an earlier fall in the Weigl titre the agglutination curves of the two reactions were parallel though the Weigl curve was at a lower level.

D IGMATIO C. Osservazioni e considerazioni sulla terapia del dermatofoi. [Observations and Discussion on the Treatment of Typhus Fever] *Boll Soc Ital di Med e Igiena Trop* (Sez. Eritrea) 1945 v 5 Nos. 5/6 29-50. English summary (4 lines)

Among the many special forms of treatment tried by the author without obvious success were —convalescent serum autohaemotherapy specific immune serum colloidal carbon intravenously congo red and cyanide of mercury mercurochrome and vaccine therapy A line of treatment which included intravenous injection of vitamin C and intramuscular injection of vitamin B₁ was tried in about 300 cases in Addis Ababa, and the author claims that this caused an obvious improvement in the general condition of the patients and that

the fatality rate was reduced from 24-27 per cent to 12-13 per cent. No absolute claim is made for the efficacy of the treatment but the method was found safe and satisfactory [See also GIUNTA and D'IGNAZIO this *Bulletin* 1939 v 36 989]

John W D Megaw

D'IGNAZIO C & CODELEONCINI E. Le vaccinazioni contro il tifo esantematico in Etiopia con il vaccino di Weigl dal 1938 al 1945 [Vaccination against Typhus Exanthematicus by Weigl's Vaccine in Abyssinia from 1938 to 1945.] *Boll. Soc. Ital. di Med. e Igiene Trop.* (Sez. Eritrea) 1945 v 5 Nos. 5/6 51-70 English summary (4 lines)

About 40 000 persons were vaccinated in Addis Ababa with a vaccine of which 16 000 doses were obtained from Weigl's laboratory and about 25 000 were prepared at Addis Ababa by workers who were personally instructed by Weigl. The incidence of the disease was greatly reduced among the vaccinated as compared with unvaccinated persons exposed to similar risks though it was suspected that many sub-clinical attacks occurred among the vaccinated. In the cases that were diagnosed the symptoms were exceedingly mild and few complications occurred.

Owing to shortage of the vaccine trials were made of doses reduced to one-half one-quarter one-eighth and even one-sixteenth of the usual amount. Among 10 000 persons vaccinated with these small doses the results did not appear to be materially different from those obtained with full doses

John W D Megaw

CODELEONCINI E. Sulla vaccinazione con escrementi di pidocchio infetto di tifo epidemico [Vaccination with the Faeces of Lice Infected with Typhus Exanthematicus.] *Boll. Soc. Ital. di Med. e Igiene Trop.* (Sez. Eritrea) 1945 v 5 Nos. 5/6 221-8 English summary (2 lines)

The paper contains a description in general terms of the preparation of a vaccine from the faeces of lice infected with louse borne typhus. The vaccine has been found effective in immunizing experimental animals and good results are claimed from the use of the vaccine on 5 000 persons. Anaphylactic disturbances are said to be thrice as frequent as with the standard Weigl vaccine which itself is regarded by most workers as obsolete because of the difficulty and cost of production.

John W D Megaw

SMITH P H. The Use of Para-Aminobenzoic Acid in Endemic (Murine) Typhus. *J. Amer. Med. Ass.* 1946 Aug 3 v 131 No 14 1114-17 1 chart. [Refs. in footnotes.]

Para-aminobenzoic acid was given to 29 patients suffering from murine typhus the dosage was 2.0 gm given every two hours with bicarbonate of soda till the temperature fell to normal. A similar number of cases "roughly comparable" served as controls. The average duration of the fever in the treated was 10.2 days and in the controls 13.2 days. There was one death in each group. The treated patient who died was 78 years old the drug was started on the 10th day and was continued for four days till the temperature became normal but the patient died of cardiac failure on the 18th day. Penicillin had been given throughout the illness from the 5th day in doses of 20 000 units every three hours and sulphadiazine was given in doses of 1.0 gm. every four hours from the 5th to the 10th day.

The author suggests that sulphonamides may be harmful he did not regard penicillin as having been helpful.

Caution is advised in cases of kidney or liver damage though no toxic effects were observed from the use of the drug in the present series or in 17 cases of other diseases in which the average total dose was 95 gm. Further trials under more rigorous control are recommended.

MACKIE T T *et al* Observations on Tsutsugamushi Disease (Scrub Typhus) in Assam and Burma. Preliminary Report. *Trans. Roy Soc Trop Med & Hyg* 1946 Aug v 40 No 1 15-46 3 figs. [39 refs.] Discussion 46-56 2 graphs. [MELLANBY K. SHORTT H. E. SAYERS M. H. P. FAIRLEY N. H. FELIX A. CLARK, R. H. P. HOLLINS C. MACKIE (in reply)]

This paper is essentially similar to the one by the same author and 13 collaborators already reviewed (see this *Bulletin* 1946 v 43 917). The larger and more detailed maps illustrating the present paper are very helpful.

Some interesting points arose in the discussion following the reading of the paper. Dr Kenneth MELLANBY said that after one negative experiment he had been able to confirm the observation that partially fed mites, when removed from their hosts reattached themselves to another host in considerable numbers; he added that badly conducted anti-rat measures might sometimes increase the risk of infection. He mentioned that benzyl benzoate as shown by later work, might be more protective than dibutyl phthalate.

Col. H. E. SHORTT enquired whether the author's findings had thrown any light on the occurrence of different serological types in India, and mentioned that among 65 Weil-Felix positive sera tested by himself in Madras 42 were of the OX19 type 16 of the OXK type and 7 of the OX8 type. The reply was that although a few atypical reactions had been observed there was no evidence of the occurrence of other forms of typhus in the area investigated.

Lt-Col. M. H. P. SAYERS showed two graphs which clearly demonstrated that the disease was definitely seasonal in south-east Asia. The curves of incidence among the troops in 1943, 1944 and 1945 showed a considerable rise in June or July reaching the maximum in August or September gradually falling to a low level by January or February and remaining low throughout February, March, April and May though the season of greatest operational activity was the first half of each year.

Brigadier Hamilton FAIRLEY told how dimethyl phthalate had been found by the Orlando group of entomologists in the U.S.A. to be the best of the known protectives against mites and to be a very effective repellent of mosquitoes; how this had been adopted on a large scale by Australian forces in 1943 and how it came to be replaced by dibutyl phthalate which, however was less repellent to mosquitoes.

Dr A. FELIX stressed the importance of the wild rat as a reservoir of infection and expressed the view that an anti-rat campaign might be even more useful in peace time than anti-mite measures. He quoted R. R. PARKER as an advocate of the opinion that susceptible wild animals were essential to the maintenance of infection in the case of the analogous disease Rocky Mountain spotted fever.

In replying Col. MACKIE did not dispute the evidence of a special seasonal incidence of the disease but emphasized the fact that the disease could occur at any season. He also disavowed any intention of minimizing the importance of rodent reservoirs of infection.

John W D Megaw

NOAD K. B. Tsutsugamushi Fever in Natives. *Med J Australia* 1946 July 6 v 2, No. 1 20-21

Details are given of two cases in which tsutsugamushi disease occurred in natives of New Guinea. The *Proteus* OXK titre rose to 1-840 in one case and

to 1-1,280 in the other. Clinically the attacks were entirely in keeping with the diagnosis. Another case was probably of the same kind but it was incompletely observed.

The author [reasonably] suggests that the supposed immunity of natives in affected areas is due to previous attacks.

John W D Megaw

Likoff W Changes in the Cardiovascular System in Scrub Typhus in Early Convalescence *Amer J Med Sci* 1946 June v 211 No 6 694-700
4 figs

A group of 100 patients whose ages ranged from 19 to 35 years was studied after an average interval of 49 days from the onset of scrub typhus. The febrile period had lasted only nine days on the average. All but one of the patients had been ambulatory for at least 14 days before examination.

Among 30 patients who complained of symptoms of rapid heart beat or other cardiovascular disturbance the pulse rate was over 100 in all but two. Among the other 70 only four had a rate of 100 or more.

An unselected group of 25 patients were tested for exercise-tolerance. 12 of these had a pulse rate which remained 10 beats higher after a resting period of two minutes and only one of the 12 had not complained of cardiovascular symptoms.

Electrocardiographic abnormalities were found in 10 patients all of whom had complained of symptoms. The chief changes found were—bundle-branch block (2) intraventricular block (1) negative T waves in two or more leads (3) splintering of the QRS (3) and secondary-degree heart block (1). In five patients the abnormalities persisted till the end of the period of observation. The most significant changes were in the three patients who had bundle-branch or intraventricular block.

No evidence was found of cardiac failure or organic valvular disease in any patient though systolic bruits were heard in the pulmonic area in six and in the mitral area in two. Electrocardiographic investigation is regarded as the most reliable method of estimating myocardial damage.

Romko B J Convalescence from Scrub Typhus. *Bull. U S Army Med Dept.* 1946 Aug v 6 No 2 167-73

A detailed examination was made of 312 patients convalescent from attacks of scrub typhus many of which had been severe. The general conclusion reached is that every patient who survives the attack will make a complete and permanent recovery.

The patients were seen between July 1942 and September 1944 they had already spent an average period of four weeks in hospitals in forward areas of New Guinea. One patient was suffering from a second attack after an interval of 10 months the previous illness had been more severe.

The patients on admission were apprehensive, they expected to be incapacitated for life and anticipated a long period of sick leave. The first step in treatment was to dispel both of these "false beliefs".

The chief findings on admission were—an average loss of weight of 15 pounds a resting pulse rate of 100 or over in 55 per cent. tremors of the outstretched hands in 60 per cent. vertigo in 25 per cent. general or local adenitis in 98 per cent. and pigmentation at the site of the eschar in all the cases, amounting to 70 per cent. in which this lesion had occurred.

After a thorough examination the patients were placed in four different classes according to their fitness for exercise. only 8 per cent. needed temporary bed treatment. During the stay in the convalescent hospital which

averaged 28.4 days all but nine of the patients had been reconditioned and were returned to full duty. Those evacuated for further treatment were suffering from various disabilities unconnected with scrub typhus.

The average period from the onset till discharge to duty was 58.9 days. It varied from 30 to 133 days. Except for persistent lymph-node enlargement, all the signs and symptoms had disappeared and no electrocardiographic abnormalities remained.

Prolonged rest in bed is strongly deprecated. The author found that convalescence was greatly hastened by starting active reconditioning treatment as early as possible after defervescence.

[Most observers will agree that the attitude of over-caution and pessimism in connexion with scrub typhus has been responsible for wastage of man power and injury to the patients but it must be noted that the fatality rate in the present series of cases had been only 4 per cent. In outbreaks with a fatality rate of 10 per cent or over the results might not have been so remarkably good.]

HICKS J D Agglutination Titres with *Bacillus proteus* (OXY) in Human Sera. *Med J Australia* 1946 July 6 v 2 No 1 19-20

Sera from four groups of persons were tested for *Proteus* OXY agglutinins — (a) 96 blood donors in Sydney (b) 100 men from a unit in New Guinea in which no cases of scrub typhus had occurred during the previous five months (c) 104 men from a unit in the same district of New Guinea, in which 29 cases of scrub typhus had occurred during the previous three months and (d) 88 natives from a nearby labour camp. Between 80 and 85 per cent of the members of all the four groups reacted at titres of 1-20 to 1-40 but in the first two groups only 6 and 3 per cent respectively reacted at 1-80 whereas in the last two groups 15 and 17 per cent reacted at this titre.

The author suggests that these figures may indicate the previous occurrence of infection among the members of the last two groups in the case of group C the infection must have been sub-clinical.

BUSTAVANTE M E VARELA G & ORTIZ MARIOTTE C II Estudios de fiebre manchada en Mexico. Fiebre manchada en la Laguna. [Studies in Rocky Mountain Spotted Fever in Mexico. *Rev Inst Salubridad y Enfermedades Trop Mexico* 1946 Mar v 7 No 1 39-48 2 graphs & 1 map [Summary in English by the authors]

The authors report the presence of Rocky Mountain Spotted Fever in La Laguna (Coahuila y Durango) Mexico. The epidemiological and experimental studies based on clinical diagnosis gave as positive results the isolation of two strains of spotted fever virus (western type of the U.S.A.) from two groups of *R. sanguineus* naturally infected.

One strain was obtained from lot 8 formed by 13 adult *R. sanguineus* gathered on the adobe walls and earth floor of a house in Granada. The second strain was obtained from lot 10 formed by three adult females of *R. sanguineus* collected on a dog of the Zaragoza Common. The confirmation of natural infection of these ticks from dogs and now in houses is important for the epidemiology of Spotted Fever in Mexico and adds *R. sanguineus* to the natural vectors of the disease in the Continent.

On the same survey were positive the complement fixation tests with sera from two persons recovered from the infection and with sera from two dogs. Lots Nos. 3 and 13 were collected in mattresses where *Rhipicephalus* lived as *Cimex* do in similar conditions.

The Laguna Region belongs by its geography to the north-central part of the Mexican high plateau which extends to the south-east of United States

MAZZOTTI L. & VARELA, G. Conservación experimental del virus de la fiebre manchada en *Ornithodoros furcosus* [Experimental Maintenance of Rocky Mountain Spotted Fever Virus in *Ornithodoros furcosus*] *Rev Inst Salubridad y Enfermedades Trop* Mexico 1946 Mar v 7 No 1 13-15 [Summary in English by the author]

A strain of virus of spotted fever isolated from Mexico was maintained experimentally during 345 days in *Ornithodoros furcosus*. This tick transmits the infection through the egg at least to the first generation

YELLOW FEVER.

DE PAULA SOUZA, G. H. Fourth Report of the Expert Commission on Quarantine. *Epidemiological Information Bull* (UNRRA Health Division) Wash 1946 July 31 v 2 No 14 580-88

The Quarantine Commission of the Expert Committee on Health of UNRRA met in New York on July 10th under the chairmanship of Dr P. G. Stock. The main item of interest in their report is an account of the controlled experiment to test the efficacy of the anti yellow fever vaccine made at the Pasteur Institute at Dakar.

Six hundred French soldiers, none of whom had been outside France or received any inoculation against yellow fever, were divided into three groups of 200 (groups A, B and C). Group A were inoculated by scarification with the Dakar vaccine, group B received the Dakar vaccine plus dry smallpox vaccine by scarification, and group C received Rockefeller 17D yellow fever vaccine by subcutaneous injection. The inoculations were given on July 4th and 5th, 1945, and blood samples were taken on August 9th, 1945, one-third of each sample being sent to Dakar for testing, one-third to the Montana Laboratory of the U.S.P.H.S. and one-third held in reserve. Ninety-two cases showed discrepancies in degree between Montana and Dakar, and the reserve sera were sent for further testing to the Yellow Fever Laboratories in Rio de Janeiro.

Final results showed that 98.94 per cent of group A, 97.93 per cent of group B and approximately 65 per cent of group C had been immunized. [This last figure is calculated from the detailed analysis of results which is shown in a fuller report on the Dakar vaccine printed in *Epidemiological Information Bulletin* Vol. 2, No. 15, an abstract of which will appear in this *Bulletin* 1947 Jan. Vol. 44 No. 1.] The results from 30 unvaccinated controls were negative in 29 and inconclusive in 1. The Commission therefore recommended approval of the Dakar vaccine under Article VI (10) of the International Sanitary Convention for Air Navigation of 1944.

The Commission also approved the yellow fever vaccine prepared at the South African Institute for Medical Research, Johannesburg (this is of the Rockefeller type). They approved this Institute and the Pasteur Institute at Dakar under Article VI (11) as Institutes for testing the potency of yellow fever vaccine.

The yellow fever endemic areas in Brazil were somewhat modified and an area 10 kilometres round the town of Asmara in Eritrea was excluded from the endemic area, subject to the monthly *Aedes* index remaining satisfactory. The questions of differentiating administratively between endemic and epidemic yellow fever areas, of extending the Convention periods for the incubation of

[December 1946]

smallpox and typhus and of the value of the immunity reaction following vaccination against smallpox were also discussed, but no decisions were reached.

[In *Epidemiological Information Bulletin* Vol. 2 No. 16 p. 689 a correction is made to a paragraph in the paper reviewed above relating to the delineated area in Brazil. This point is not referred to in the above abstract but the correction reads as follows: — Attention is called to a printing error in *Epidemiological Information Bulletin* Vol. II No. 14 p. 384 line 21 instead of 15° read 5° parallel of latitude. —Ed

BRITISH GUIANA. Report on the Yellow Fever Control Service of the Medical Department, British Guiana, for the Year 1945, including an Historical Résumé from its Origin to Date. BEVIER, G. M.D. Chief Officer] 26 mimeographed pp with Appendices I & II

It is known that jungle yellow fever occurs in the inland parts of British Guiana. In 1930 and 1940 NEATH this *Bulletin* 1940 v. 37 90 1941 v. 38 67 reported that nearly 3% per cent of 506 blood specimens from the interior gave positive protection tests and one-fifth of these positive specimens were from people under 20 years of age. But the positive specimens were entirely from the interior and the point is made that although in the past (up to about 1914) the disease occurred in the coastal areas there is no evidence that it has been endemic there since then. The populated coastal region is separated from the inland jungle area by a wide zone of practically uninhabited country, communication between the interior and the sea is limited to river or air traffic. There is a focus of yellow fever in Venezuela adjacent to the boundary of British Guiana.

The yellow fever control service in British Guiana is concerned most particularly with the control of *Aedes aegypti* on the coast especially in the ports and airports. Georgetown is the last port of call for many ships and aircraft leaving the mainland for the islands and countries to the north. One viscerotomypost has been established in the jungle country, and others are projected, but in the meantime mosquito control has been developed.

Aedes aegypti is common in Georgetown, and control measures have been in force for some years. A trained staff now exists and public co-operation is fairly good. Inspectors visit all houses and have become proficient in detecting breeding places of *Aedes aegypti* particularly those likely to be overlooked by the householders—vases, water-containers, roof gutters and the like. In the controlled area there are 29 102 premises. This country receives a heavy rainfall of 80-120 inches.

The most useful index of the prevalence of *Aedes aegypti* is given by the premise breeding index which shows the percentage of premises in which breeding is found. This is based on the reports of inspectors, who make weekly visits to the premises in the area. A group of houses which one inspector can visit between Monday morning and Friday evening constitutes a zone. Six zones constitute a District which is under the control of a Chief Inspector who is expected to re-inspect about 10 per cent of the houses in each zone. There are also special services for distributing larvivorous fish, for dealing with high tanks, and with roof gutters, for culing drains and other collections of water and for classification of mosquitoes caught. Squads whose duty it is to capture adult *Aedes aegypti* have become increasingly important. The most sensitive indication of breeding is the finding of adults in houses, and they can usually be found, if present by trained inspectors. The roof gutter problem has been costly to solve but with special training and equipment periscopes ladders, etc. a great improvement has been made. A serious complication of this problem is

the fact that eggs of *Aedes aegypti* can persist in the dry state for over a year and that they can hatch out within a very short time if they are wetted. In Brazil these dried eggs are killed in gutters by means of a blow flame but in Georgetown the risk of fire was too great for this. The water supply of Georgetown and other places depends very largely on roof collection by gutters and storage in barrels and drums. The latter are also a source of breeding and one of the most difficult tasks has been to enforce mosquito-proofing or sealing of such containers.

Insecticides have been used, especially DDT in houses, trains, aircraft and motor-cars with useful results. One point brought out is that when DDT is (wrongly) used to spray the air of a room as is the custom with pyrethrum products, the result is not so satisfactory as when it is sprayed on the walls. Records are given of various experiments with DDT. Phenothiazine is useful for water containers—it kills insects in dilutions approaching those of chlorine in drinking water and is harmless [in those dilutions] to higher animals.

Aircraft are inspected and sprayed in quite a large proportion living insects have been found and this is causing concern to public health, agricultural and veterinary officials alike though no living *Aedes aegypti* or anophelines were recorded during 1944 and the first half of 1945. Vaccination against yellow fever is available free of charge and any person arriving at the coast from the interior is kept under surveillance for six days.

In 1945 there were 207 persons employed in the Yellow Fever Service including probationer inspectors. The financing of the scheme is explained from September 1939 to October 1, 1945. 359 688 dollars had been expended mostly from Government and Colonial Development and Welfare Funds but with a contribution from the Rockefeller Foundation. Tribute is paid to the Foundation for the scientific assistance it has given.

Plans for the future are set out and there is an interesting Appendix on yellow fever in British Guiana.

DENGUE AND ALLIED FEVERS

HITTI J. K. & KHAIRALLAH A. A. A Report on the Recent Epidemic of Dengue in Beirut, Lebanon, and some of its Complications. *J. Palestine Arab Med Ass.* 1946 July v 1 No 5 150-53

An exceptionally severe epidemic of dengue occurred in Beirut in 1945 when the lateness of the rains and of the advent of the cold weather provided conditions in which the disappearance of the disease was delayed.

Early in the course of the epidemic a tendency to haemorrhage was observed in several patients. petechiae were often seen. Among the other complications were corneal ulceration, meningismus (often), post febrile neuralgia (several cases), otitis media (fairly common) and acute gastritis (many cases). Including deaths from complications the fatality rate was about one per cent.

PLAGUE.

DEVIGNAT R. Aspects de l'épidémiologie de la peste au Lac Albert. [Epidemiology of Plague at Lake Albert.] *Ann Soc Belge de Méd Trop* 1946 June 30 v 26 Nos. 1/2 13-54 4 figs. [21 refs.]

This publication is an elaboration and application of a theory and scheme already propounded [see this *Bulletin* 1946 v 43 647] which gave a linear

equation $Q = h [k(i+t) + k(i+t)^2 + k^2(i+t)^2]$ for the determination of the common indices Q_1 , Q_2 , Q_3 of epidemiologic and epizootic transmissibility of plague. The author himself warns his readers that his is an attempt to systematise epidemiology and that the data obtained will be of the order only of first approximations. Practical applications of the method are given in the second chapter and in the third it is shown how the three fundamental planes of plague activity have been studied. Without attaching exaggerated exactitude to the figures obtained it may be concluded that as regards Lake Albert the conditions there of transmissibility were favourable both on the sylvatic and the domestic plane and that there was no difficulty in passing from the one plane to the other. The persistence or endemicity of plague was thus easy to explain in spite of the long silences that can occur quantitatively by a fifty fold decrease of the Q index. Moreover with the arrival of plague on the human plane it is even more difficult for plague transmitted by fleas to pass from man to man since the local variety of human flea *Ctenocephalides felis strongylus* is stated not to be a plague vector. Pneumonic plague is expressly excluded from these epidemiological investigations.

BACILLARY DYSENTERY

MACGREGOR, I. Acute Enteritis in Subtropical Climates. *Brit Med J* 1946 Aug 17 225-6 1 graph.

Observation of 435 cases of upper respiratory infection (acute nasal catarrh and acute sinusitis) and 357 cases of acute enteritis (simple diarrhoea not of specific dysenteric origin) over a period of 80 weeks suggested by the close correlation of the weekly incidence of the two conditions that the cause of acute enteritis might be related to the causative organism of upper respiratory infections.

Sandstorms and *khamsins* (the strong wind of Egypt) which produced a marked increase in the incidence of acute exacerbations of chronic rhinitis and sinusitis appeared to cause no increase in the incidence of fresh upper respiratory infections or in that of acute enteritis suggesting thereby that mere mechanical irritation of the bowel does not suffice to explain the enteritis. There also appeared to be no connexion between the incidence of acute enteritis and any one specific ration issue. Sudden cold spells of weather or a sudden fall in the temperature at night however increased not only the incidence of acute respiratory infections but also that of acute enteritis.

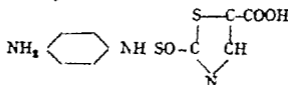

Following the view that acute gastro-enteritis of children is probably due to virus invasion of the intestinal tract rendering the mucous membrane more vulnerable to the ordinary bacterial flora of the region, the author suggests that the absence of an associated gastritis could be explained on the ground that the virus lodging first in the nasopharynx reaches the intestine by invasion of the blood stream that it passes directly from the nasopharynx to the intestine.

through the oesophagus and stomach but that the higher resistance of the adult gastric mucosa prevents the development of gastritis or that in the adult stomach possibly owing to its high pH there are not the organisms to attack the mucosa when it has been damaged.

F Murgatroyd

WINNER P S An Intestinal Antiseptic 2-Sulfanilamido-5-Carboxythiazole
Science 1946 June 21 719-20

2-sulphanilamido-5-carboxythiazole has the formula —

It is a white crystalline solid slightly soluble in water (40 mgm. in 100 cc. at 24°C) giving an acid solution. The solubilities of the mono and disodium salts are greater than 30 per cent. the pH of saturated solutions being 5.4 and 8.5 respectively. The solubility of sodium salt of the acetyl derivative is 8 per cent. so that there is little danger of the kidney being blocked by a deposit of crystals. When tested *in vitro* against bacteria such as streptococcus pneumococcus staphylococcus and enteric organisms its bacteriostatic activity was usually greater than that of sulphanilamide and equal or slightly inferior to that of sulphathiazole and sulphadiazine.

When given in single doses to mice the LD₅₀ is 8.0 gm. per kgm. by mouth or 5.0–6.0 gm. per kgm. by intraperitoneal administration. The chronic toxicity in mice rabbits and dogs was much less than that of the readily absorbed sulphonamides and was comparable to that of succinyl sulphathiazole. When given to man (0.25 gm. per kgm. per day for 5 days) the blood concentration is always low (less than 1 mgm. per 100 cc.) about 3–11 per cent of the amount taken by mouth is excreted in the urine. In 4 men taking this dose the number of coliform bacilli in the faeces was reduced to 10–1 000 organisms per gm. of wet faeces in 24–48 hours. It is claimed that the new drug is more effective than succinyl sulphathiazole in this respect. HARRIS and FINLAND (*Proc Soc Exper Biol & Med.* 1945 v 53 116) have tried it in cases of bacillary dysentery. They found it to be absorbed into the blood only in small amounts to be non-toxic and to be effective in treating the dysentery.

AMOEBIASIS AND INTESTINAL PROTOZOAL INFECTIONS.

LEITMAN M Z. [The Virulence of various Strains of the Dysentery Amoeba and the Effect of Bile on the Infestation by Protozoa.] *Med Parasit & Parasitic Dis* Moscow 1945 [1946] v 14 No 6 39–44 [In Russian]

With a view to throwing some light on the epidemiological rôle of symptomless carriers of *Entamoeba histolytica* the author carried out a series of experiments to test the virulence of various strains for kittens and pups. The following four strains were used — (1) from a symptomless carrier (2) from a chronic case during the latent period (3 and 4) from cases of acute amoebic dysentery.

The animals (total number 46) were inoculated either *per os*—with cysts or *per rectum*—with the active amoebae. Half of the animals were inoculated without any preliminary treatment whereas the other half received a dose of bile *per rectum* (2 cc. in kittens 3 cc. in pups) preceded by an enema. In the

first group only 11 out of 23 (48 per cent.) acquired an infection, and there was no essential difference in the incubation period, course of infection and intestinal lesions produced by the four strains. However in the second group (with bile) the results were more striking, the number of infected animals being 16 (70 per cent.) The effect of bile treatment upon infectivity was especially marked in those strains which proved to be less virulent when inoculated without bile.

The effect of bile upon the infectivity of protozoa was also tested by inoculating white rats with a strain of *Balantidium coli* isolated from a symptomless human carrier. Whereas among 17 rats inoculated without bile only one (5.9 per cent.) became infected, in a group of 15 rats treated with bile 5 (33.3 per cent.) acquired an infection.

Bile irritates the mucous membrane of the intestine producing hyperaemia, abundant secretion of mucus and desquamation of the epithelium. These changes apparently sensitize the intestinal wall rendering the experimental animals more susceptible to infection with intestinal protozoa. It is concluded that the results of these experiments have again demonstrated that strains of *E. histolytica* isolated from patients suffering from dysentery are not less virulent than those originating from symptomless carriers.

While this conclusion may be right it should be emphasized that, like previous experiments of this kind, it is based on and applies to the behaviour of *E. histolytica* in non natural hosts.

LINDSKOG G E & WALTERS W. *Surgical Aspects of Amoebic Dysentery*
J Amer Med Ass 1946 May 11 v 131 No 2 92-5 3 figs
 C A Boore

This is a report of three cases of amoebic hepatic abscess and one of amoebic granuloma of the caecum occurring among personnel of the U.S. Army and Navy returning after service in the tropics. In one of the cases the abscess perforated through the diaphragm to the pleuro-pulmonary region and in another a right hepatic abscess recurred after open drainage but subsided after a course of penicillin and emetine without further operation. The indications for open drainage in preference to aspiration are discussed. The amoeboma occurred in a patient who had suffered from acute amoebic dysentery twelve months previously for which he had been treated apparently successfully with emetine and carbamezole. He relapsed six months later and after further medical treatment with only slight improvement a movable tumour appeared in the right lower quadrant and X-ray studies revealed a constrictive filling defect at the ileo-caecal junction. Right hemicolectomy was performed and was followed by uneventful recovery. In none of these four cases were amoebae or cysts demonstrated in the stools.

- i. SMITH M J. Confusion of Amoeboma with Carcinoma. *Lancet* 1946 Sept 14 376-8 1 fig
- ii. HAWK P. Amoeboma and Carcinoma. [Correspondence] *Ibid* 1946 Oct. 5 508-9

1. Among the many abdominal cases admitted to the Ministry of Pensions Hospital at Roehampton, London there were some in which left iliac colostomy had been performed for no ascertainable reason. A factor common to all was that they all had suffered from amoebic dysentery and all except one had been treated by emetine injections. The logical conclusion was that an amoeboma had been mistaken for carcinoma. Radical surgery in such cases such as resection of the colon or excision of the rectum may be serious because in the absence of anti-amoebic treatment a fatal outcome is almost invariable.

Occasionally as in the case recorded by MORGAN [see this *Bulletin* 1945 v. 42 124] amoeboma and carcinoma may coexist.

Amoebiasis of skin and subcutaneous tissues may develop after colostomy as in the case cited in this paper. This patient was admitted with the diagnosis of rectal carcinoma. He had served in many countries but had never had dysentery. As the result he claimed, of lifting heavy shells a lump appeared in the left lower abdomen an occurrence associated with diarrhoea, tenesmus and piles. On admission to hospital no amoebae having been demonstrated in the faeces a left iliac colostomy was performed. Subsequently a large infected area appeared in the vicinity of the bowel and further spread was prevented by diathermy excision.

After closure of the colostomy the wound became acutely inflamed and broke down with parting of the sutures in the bowel and re-establishment of the colostomy. During the next four weeks the infected area continued to spread and the patient's condition was rapidly deteriorating when *E. histolytica* was demonstrated in the faeces. On intramuscular emetine treatment reinforced by diodoquin (4 tablets daily for ten days) the stools became clear of amoebae and the wound rapidly scarred over.

Two cases of the converse error are recorded in which carcinoma of the rectum had been treated for dysentery in both rectal digital examination had been omitted.

ii. This correspondent refers to the rare existence of amoeboma of the rectum which may be present as an ulcer or as a papilliferous overgrowth, and which may be indistinguishable from carcinoma.

A course of emetine before resort is had to operation is a valuable aid to diagnosis but only a complete resolution of the amoeboma can be accepted as proof of a purely amoebic origin by this means.

The author has seen six of these cases during four years military service. Five resolved on medical treatment. The sixth was diagnosed as an advanced carcinoma of the rectum colostomy was proposed, but a proctoscopic examination on the operation table revealed the presence of *E. histolytica*. Operation was postponed and the patient died despite a few days of emetine treatment. Post mortem examination showed how futile a colostomy would have proved, for the whole colon was diffusely ulcerated.

Whilst colostomy may be required where other methods fail a note of warning is sounded regarding too hasty embarkation on this procedure owing to the risk of spreading amoebic infection and to serious hepatic complications.

P Manson Bahr

CROPPER, C. F. J. Amoeboma of the Hepatic Flexure. [Memoranda.] *Brit Med J* 1946 June 29 888.

The case reported is that of a Gurkha, aged 23 with no previous history of ill health. For three weeks he had complained of pain in the right hypochondrium and of evening pyrexia, unaccompanied by bowel symptoms. In the right hypochondrium was a rounded, hard, tender swelling 3½" in diameter which appeared to be unconnected with the liver and was attached to the right rectus. The stools were repeatedly negative for exudate, cysts and ova the white cell count was 14 000 per cmm. with 80 per cent. polymorphs and sigmoidoscopy showed typical amoebic ulceration, but no scrapings were taken. Skiagrams after a barium enema showed arrest of the barium by a constriction at the hepatic flexure with delayed filling of the ascending colon and caecum and retention of the opaque medium in that part of the intestine after evacuation of the enema. A course of emetine and penicillin led to rapid resolution of the swelling and a skiagram three weeks later showed a normal large intestine.

on sigmoidoscopy all the ulcers were found to be healed. Throughout the illness there were never any dysenteric symptoms.

W. L. Harrell

HALAWANI A. NOR EL DIN G. & AWAT A. I. Treatment of Amoebic Dysentery with Sulphaguandine as compared with Emetine and other Antidysenteric Drugs. *J. Roy. Egyptian Med. Ass.* 1946 Jan-Feb., v 29 Nos 1/2, 13-18

"(1) Sulphaguandine exerts a favourable effect on the clinical manifestations of amoebic dysentery, but relapses occur shortly after cessation of treatment.

(2) The average time after which relapses occur after sulphaguandine is approximately ten days while this time after emetine treatment is as long as 21 to 27 days.

(3) The action of sulphaguandine is solely on the vegetative forms. The cysts are not affected by this drug. In some cases under sulphaguandine treatment the amoebae changed from the vegetative forms to the cystic stages.

"(4) Resistant cases have been found to benefit from a combined treatment of emetine and sulphaguandine.

(5) The effect of enteronitroform and disenteran on the vegetative forms of *E. histolytica* was found inferior to emetine. Their effect was mainly on the cysts."

OSTROVSKY I. G. [On the Protozoal Fauna of the Intestine in Post Dysenteric Colitis (Dysentery Chronica).] *Med. Parazit. & Parazit. Daz.* Moscow 1945 (1946) v 14 No 6 44-6 [In Russian]

The author describes the results of a survey in Stalinabad (Middle Asia) of the protozoal fauna of hospital patients (total 115) suffering from chronic (post-dysenteric) colitis. The examination was carried out mainly in fresh and iodine-treated faecal preparations and sometimes in fixed and stained material. When the results were negative the faeces were examined repeatedly (up to 6 times, and on the average 2.6 times). Only 49.6 per cent. of the patients examined were infected with intestinal protozoa in most cases with one or two species (24.3 and 17.4 per cent. respectively). The relative incidence of the various parasites was as follows: *Entamoeba coli* 20.9 per cent. *Chilomastix* 20 per cent. *Trichomonas* 18.3 per cent. *Giardia* 12.2 per cent. *Iodamoeba* 7.8 per cent. *Endolimax* 4.3 per cent. *Entamoeba histolytica* 2.6 per cent.

In the course of repeated examinations the frequency of the occurrence of different parasites in the same person varied, the findings in 297 examinations of 115 patients being distributed as follows: *Chilomastix* 32 times, *E. coli* 29 times, *Trichomonas* 23 times, *Giardia* 23 times, *Iodamoeba* 9 times, *Endolimax* 5 times, *E. histolytica* 3 times. The author compares his findings with those in 743 healthy adults examined during the same period by another worker whose results were as follows: *E. coli* 37.9 per cent. *Chilomastix* 15.8 per cent. *Trichomonas* 16.1 per cent. *Giardia* 17.4 per cent. *Iodamoeba* 22.1 per cent. *Endolimax* 7.9 per cent. *E. histolytica* 0.4 per cent. *Balanulium* 0.3 per cent. This comparison showed that in cases of colitis the finding of *E. coli*, *Iodamoeba* and *Endolimax* is reduced to half, while *Chilomastix* and *Trichomonas* are almost as common in cases of colitis as in healthy intestines. This confirms the results obtained by other Russian workers who found that there was a marked diminution of the protozoal fauna when the normal functions of the bowel were disturbed.

LEITMAN M Z & VITLINSKAYA I A [Treatment of Carriers of Pathogenic Protozoa.] *Med Parasit & Parasitic Dis* Moscow 1945 [1946] v 14 No 6 46-50 [In Russian]

In view of the epidemiological rôle of carriers of *Entamoeba histolytica* in the transmission of the infection and of the possible transition from symptomless infection to clinical forms of the disease the authors have carried out an experiment on the treatment of cyst-carriers of *E. histolytica* in Tashkent. A preliminary examination of 1 002 persons revealed the following incidence of pathogenic intestinal protozoa: *E. histolytica* 127 (12.7 per cent), *Giardia* 139 (13.9 per cent), *Isospora* 7 (0.7 per cent), *Balantidium* 1 (0.1 per cent). The infected persons were dealt with as follows: one group of *E. histolytica* carriers was treated with yatren (adults had 4 courses of 0.5 gm administered twice a day for 5 days with intervals of 5 days between the courses; children had 4 courses of 0.25 gm a day for 6 days with intervals of 6 days); a second group of *E. histolytica* carriers was treated with osarsol (for adults 5 courses of 0.25 gm, thrice a day for 5 days with intervals of 5 days; children had 5 courses dosage as for yatren); a third group comprising *Giardia* carriers was treated with acrinine [=mepacrine] (adults received 0.1 gm thrice daily for 5 days followed by a 10-days interval after which the same dose was repeated for 3 days again followed by an interval of 10 days and a repetition of treatment for 3 days; children were given 0.1 gm daily for one month).

Throughout the course of treatment the stools of the carriers were examined once a week and subsequently once a month for five months. During the first period of observation *E. histolytica* cysts were still present in 20.4 per cent of carriers treated with yatren and in 14.4 per cent of those treated with osarsol but the percentage of positive results fell considerably in the course of the first three months. However from the fourth month it began to rise again especially in the yatren group reaching 28.6 per cent after five months, i.e. it was higher than during the period of treatment but in the osarsol group an increase of positive findings was noted only after five months. In the group of *Giardia* carriers treated with acrinine there was also at first a diminution in the number of cyst passers followed by an increase after three months reaching 27.7 per cent at the end of the fourth month and 27.5 per cent after the fifth. On the whole in the majority of carriers the treatment was effective for only 3-4 months after which cysts again appeared in over 33 per cent of the cases. It is concluded that carriers among food handlers can be dealt with effectively only if treated at least twice a year.

ACOSTA MATIENZO Josefina Incidence of Intestinal Protozoa among Patients of the University Hospital at San Juan, Puerto Rico. *Puerto Rico J. Pub Health & Trop Med* 1946 June v 21 No 4 369-71 [Spanish version 372-5.]

HALAWANI A. & EL KORDY M. I. A Case of Human Coccidiosis. *J. Roy Egyptian Med Ass* 1946 Jan.-Feb. v 29 Nos. 1/2, 32.

MALDONADO J. F. *Isospora hominis* Fantham, 1917, in Puerto Rico. A Report of the First Case observed. *Puerto Rico J. Pub Health & Trop Med* 1946 June v 21 No 4 397-400 2 figs. [Spanish version 401-4.]

Isospora hominis occurs in Puerto Rico as demonstrated by the discovery of a case in which the chances of infection were entirely local. The presence of *S. mansoni* obscured the possible effects of the coccidium on the patient, but there is the possibility that his recent intestinal disorders may be ascribed to

this parasite. The course and general character of the infection were similar to those described by most authors but the action of fuadin on the coccidiosis was questionable."

RELAPSING FEVER AND OTHER SPIROCHAETOSIS

RAFTI A. Sur la fièvre récurrente sporadique en Iran. Etude expérimentale de *Spirochaeta persica* (deuxième note) On Sporadic Relapsing Fever in Iran. An Experimental Study of *Spirochaeta persica* (2nd Note) Arch Inst d'Hessarek Teheran 1946 Jan v 2 No. 37-42.

The author in collaboration with DELRY [see this Bulletin 1939 v 36, 757], recorded the existence of human relapsing fever in the north and north-west of Iran. They also showed that the causal agent was *Spirochaeta persica* and that it was transmitted by all stages of *Ornithodoros tholozani*.

Subsequently the disease has been found in other parts of Iran and especially in Teheran and 16 cases have been observed at the Hessarek Institute in the last five years. As a rule the patients recovered spontaneously and treatment with novarsenobenzol was efficacious.

The author has studied the infection in guinea-pigs, rabbits, rats, and mice all of which may be infected, not only by the injection of blood containing spirochaetes, but also by the bites of infected ticks. One in five of ticks collected in infected houses produced infection when fed on normal rats. The infection was transmitted hereditarily to the offspring of infected female ticks. Adults were found to be still infective after 1 175 days, and nymphs infected in this stage were stated to be still infective after 1 403 days. Ticks emerging from eggs laid by infected parents were still infective 2 066 days after the parent was infected.

The spirochaete was found to survive in the brain of white rats up to 593 days. In a footnote the author corrects an error in their earlier paper and states that residual infections in the brain of rabbits, guinea-pigs, dogs and sheep have not yet been demonstrated.

E. Hindle

ANDERSON E. S. Penicillin in the Treatment of Experimental Relapsing Fever in Rats. Trans Roy Soc Trop Med & Hyg 1946, Aug v 40 No 1 83-100.

This is a record of experiments carried out to test the effect of penicillin in white rats inoculated with a Cyprus strain of *Spirochaeta recurrentis* which in nature is transmitted by *Ornithodoros tholozani* and is apparently insensitive to arsenicals.

One group of rats was given massive doses of penicillin either at the time of inoculation of spirochaetes or three hours later or at both these times. This treatment was quite ineffective in preventing infection, but an intermittent prophylactic dose maintained three-hourly for 78 hours seemed to prevent the development of the disease.

Once spirochaetes had appeared in the circulation, intermittent dosage did not control the disease, and the persistence of the infection in the brain of a rat was not influenced by relatively huge doses of penicillin administered early in the disease.

The *in vitro* exposure of spirochaetes to high concentrations of penicillin did not affect their structure, motility or infectivity.

Professor S. ADLER and Dr R. ASHREI (personal communication to the author) using a similar strain of spirochaete have carried out a comparable

set of experiments also with negative results. It would seem therefore that the Cyprus strain of *S. recurrentis* is not only resistant to arsenicals but also to penicillin

RANDOLPH N. M. DDT to control the Relapsing Fever Tick. *J. Econom. Entom.* 1946 June v 39 No 3 396

The results as given in table I show that DDT sprays of 10 per cent and 20 per cent strengths were effective in killing relapsing fever ticks. Applying DDT spray directly to the tick does not appear to increase the effect of the insecticide. DDT of high concentrations is a promising insecticide for controlling these ticks however the cost and feasibility of applying it to natural conditions may be prohibitive. Field experiments are being conducted.

GUIMARÃES, F. N. Ensaios terapêuticos com penicilina. V. Bouba (Framboesia pian yaws). I. Dose curativa mínima. II. Redução do número de injeções diárias. III. Redução de tempo de tratamento pelo emprego de doses mais elevadas. [Penicillin Therapy V Yaws.] *Mém. Inst. Oswaldo Cruz.* 1945 Aug v 43 No 1 31-58 15 figs. [Summary in English by the author.]

This report belongs to the series of works carried out at Oswaldo Cruz Institute on the treatment of treponematoses with penicillin.

The present report deals with investigations performed in order to ascertain the following points:—(1) the minimal curative doses for the initial lesions of yaws; (2) the effect of reduction of the number of injections each day to verify the possibility of application of penicillin in the prophylaxis of yaws in rural zones; (3) reduction of the time of treatment by application of high doses.

- (1) With doses of 150 and 100 Oxford units every four hours clinical recovery was obtained after 17 days of treatment. With 50 O. u. during 40 days clinical recovery was not obtained.
- (2) (a) With 3 injections of 400 O. u. each day (at 6, 12 and 18 hours) clinical recovery was obtained after 14 to 16 days.
- (b) with 2 injections of 400 O. u. each day (at 6 and 18 hours) clinical recovery was obtained after 16 to 23 days.
- (c) with 1 injection of 1,600 and 3,200 each day clinical recovery was obtained after 30 and 20 days.

[December 1946]

obtained by biopsy showed the usual leprotic tissue with the organisms. When these tumours are numerous little can be done beyond the giving of chemotherapy but if they are few good results may be obtained by removal of them.

GRUEYFELDER, B. & LASCH W. Leprosy of the Nose in relation to the Sexual Apparatus. *Acta Med Orientalia (Palestine & Near East Med J)* 1946 May v 5 No 5 156-61 [43 refs.]

The authors have previously found in cases of infantile cryptorchidism anomalies in the olfactory sphere. In the present paper they discuss a similar relationship in cases of leprosy and they quote from a number of writers in support of this view. They have noted, in male lepers effeminate features usually only met with in eunuchs and in nodular and mixed cases remarkably early reduction of sexual functions is to be observed. Those who are attacked before the age of puberty may show arrest in the development of the testis and of secondary sex characters with according to GURCK, absolute impotence or loss of sexual powers in 85.4 per cent of nodular cases. The sexual apparatus of women in nodular cases is reported to be affected in the same way as in men, with resulting dysmenorrhoea and sterility and in females attacked young there is absence of menstruation later on. It is in just these nodular cases that the nasal mucous membrane is also affected in leprosy, as shown by references to papers of older writers. The analogous behaviour of the sexual system and the nose indicates that something in common connects them, but further investigations are required to enable the precise relationship to be determined.

L Rogers

PORTUGAL H & ROCHA, G L. Juxta-Articular Nodes of Leprous Origin. *Arch Dermal & Syph* 1946 Mar v 53 No 5 471-6 5 figs. [Refs. in footnotes]

This condition is most commonly seen in syphilis and yaws it has also occasionally been observed in tuberculous. The author now records a case of leprosy with a nodule the size of a chestnut near the upper epiphysis of the right ulna, together with other leprosy nodules in various parts of the body. On excision and microscopical examination as shown by illustrations, it was found to be fibrous in nature with numerous capillaries and small cellular infiltrates. The central zone showed numerous lepra cells of Virchow with many acid fast bacilli typical of a leproma.

HARLEY R D. Ocular Leprosy in Panama. A Study of 150 Cases. *Amer J Ophthalmol* 1946 Mar v 29 No 3 295-316 19 figs. [37 refs.]

One hundred and fifty cases of ocular leprosy are reviewed by Harley. Twenty-six per cent were classified as belonging to the anaesthetic form and seventy-four per cent were classified as belonging to the nodular and anaesthetic types. Nearly all the mixed cases showed a positive blood test for syphilis whilst the neural cases were less likely to give a positive test unless there was an acute tuberculous reaction. It is generally agreed that lesions of the eye present a very real and serious complication in leprosy and ocular involvement varies from 20 to 100 per cent. of all patients when the different forms of the disease are taken into account. In Panama 80 per cent of the leprosy patients were found to have ocular involvement, not including the adnexa. If the adnexa were included, it may be assumed that in predominantly nodular leprosy all but those in the first few years of their disease had involvement about the

eyes Some form of ocular leprosy will eventually occur if the patient lives long enough. The 10 per cent of eyes free from the disease were found exclusively in recent cases. Among all the organs involved in leprosy, the ocular lesions appeared to cause more complaints than any others.

Not only is the method of transmission of leprosy in dispute but there is still much speculation as to the medium of transfer. The portal of entry for the ocular invasion is also in question. By some it is believed that the bacilli enter the eye externally from the conjunctiva or episcleral tissues. Most workers believe that the ocular infection is secondary to a haematogenous spread. Fuchs found the primary ocular lesions in the anterior part of the ciliary body and major circle of the iris and is of opinion that the bacilli may appear in healthy tissues but do not necessarily affect them. In the case of five sectioned eyes it was shown that inflammation occurred in the perilimbal episclera and the longitudinal fibres of the ciliary muscle extending back to the ora serrata but no further. In all cases the cyclitis appeared to be an older inflammation than the episcleritis which added to the evidence of an endogenous spread. There appear to be two factors exogenous and endogenous which seemed to be acting simultaneously in the disease. In some eyes one factor often predominates over the other. The disease primarily strikes the anterior segment of the eye and it is in this region that bacilli are most often encountered. It is unusual to see any pronounced ocular complication not accompanied by varying degrees of nasal mucous-membrane ulceration and perforation. The possibility of an ascending infection by way of the naso-lachrymal duct is to be considered, but purulent dacryocystitis is not seen as commonly as might be suspected.

In the series of 150 patients 13 per cent. were found to be totally blind in one or both eyes 41 per cent. had vision of 6/60 or less in one or both eyes 43 per cent. had normal vision in both eyes 10 per cent. had normal vision in one eye. Fifty four per cent. therefore may be regarded as the percentage with severe ocular complications of leprosy. The adnexa of the eye, the region of the eyebrows and eyelids are involved with considerable frequency. Fifty per cent. of the patients had hypertrophy of the skin of the brows or cutaneous nodules with varying degrees of loss of hair of the eyebrows or lashes (madarosis). In nodular leprosy formation of nodules about the outer eyebrows is common. The margin of the eyelid usually the upper may be attacked by nodules and these nodules may ulcerate a diffuse infiltration of the eyelid margins may occur which gives the edges a rolled thickened appearance (tylosis).

In anaesthetic leprosy isolated areas of diminished or absent sensitivity occur in the skin about the eyes. These may differ slightly in colour from the rest of the skin. In 10 per cent of cases there was paresis of the orbicularis palpebrarum (lagophthalmos) to the extent that there was incomplete closure of the lids. Fully another 10 per cent of patients showed weakness of the lid closure. In each case the involvement was bilateral but differed in intensity between the right and left side. The cases of lagophthalmos were in the purely neural and mixed types alike. The affection appeared to be a pure neural one and involved the eyelids out of proportion to the other structures. Ectropion resulting from lagophthalmos was found in most of these cases. Exposure keratitis and excessive lachrymation are also the usual sequelae.

Chronic conjunctivitis occurred in 40 per cent. of the cases and was of the catarrhal type with profuse mucopurulent discharge. This caused less inconvenience than one would expect probably because of the diminished sensitivity of the conjunctiva and cornea. Complete absence of sensation of the conjunctiva was however never demonstrated. Nodules on the conjunctiva were found in only two of the 150 cases, and the conjunctiva is apparently more immune than the other ocular structures.

The cornea is the most vulnerable of the ocular tissues and was involved in 87 cases frequently it was the only site in which any pathological change could be seen. The most commonly observed corneal lesion was superficial keratitis which occurred in over 34 per cent. of all cases. This usually began as a light milky haze punctuated by tiny white spots at the superior limbus. The lower margin was well delineated by a wavy line and was 2 to 3 mm. above the pupillary centre of the cornea, so that vision was not impaired. Pannus is usually present. In 23 cases an interstitial keratitis was present. In three cases the giant leprooma occurred this is the most unusual lesion of the cornea. It is engrafted on the cornea from a superficial keratitis and is teeming with lepra bacilli. Beading of the corneal nerves was found in five cases. Corneal anaesthesia was found to be rare.

Second only to the cornea the iris is the structure most frequently involved in ocular leprosy. Iritis or its sequelae were recognized in over 50 per cent. of the cases. It was usually bilateral. Iris atrophy is common in the older cases. In old iritis the tiny lepromata were seen in 26 per cent. of the cases. Typically they were greyish-yellow pedunculated pin-point bodies about the pupillary border of the iris. The ciliary body and the anterior choroid were also probably involved but this was more difficult to demonstrate clinically. Cyclitic membranes were found in advanced cases and leprosy involvement of the ciliary body caused destruction of the zonule and subluxation of the lens. Secondary glaucoma is not common contrary to what one might suspect. Leprosy of the sclera is nearly always secondary to limbal involvement. Lens opacities secondary to phacolytic iritis occurred in 20 per cent. of cases. Ophthalmoscopic examination of the fundi of 50 patients produced negative results, and proved that ocular leprosy is characteristically a disease of the anterior segment.

Prophylaxis for leprosy eyes through protection with dark glasses is advised. Treatment is largely confined to palliative measures. Thyrocin solution (Squibb) used as drops, may be of aid in helping to clear corneal infiltration. The leprosy patient withstands surgery of the eye well, despite the chronic inflammation. Surgery of the eyelids produces gratifying results.

NEVES, A. *Sarna crostosa. [Scabies in Leprosy]* *Rev. Brasileira Leprologia* S. Paulo. 1945 Dec. v 13 No 4 251-60 11 figs. [15 refs.]

[This and the following three abstracts deal with papers read at the Leprosy Congress held at Minas Geraes in June 1945.] Two cases are recorded of the lepromatous type of leprosy associated with scabies infestation. The hands forearms buttocks thighs and legs and, in one case the left scapular region, were involved. Locally there was incrustation and much itching and the fingers showed deep fissures (clearly depicted in a photograph). The itch mite and also acid-fast bacteria were seen by microscopical examination. Association of scabies with the nervous type of leprosy has also been reported and the author states that the anaesthetic leprotic condition does not affect the infestation by scabies.

ALEXO, Joséfido & COELHO, J. T. *Considerações sobre a reação de Montenegro em doentes de lepra. [The Montenegro Reaction in Leprosy]* *Rev. Brasileira Leprologia*. S. Paulo. 1945 Dec. v 13 No 4 263-6 1 fig.

As regards the intradermal reaction of Montenegro ARANTES has stated [see this *Bulletin* 1942, v 39 170] (1) That it is always negative in lepers with no history of leishmania infection. (2) that in lepers who had suffered years

before from leishmaniasis it was strongly positive (3) that leprosy does not affect the reaction in patients cured of leishmaniasis (4) that those with leishmania in an ulcer do not give the reaction

The authors have not been able to confirm the last of these statements and quote the case of a leprosy subject aged 39 years of the L_1N_1 type with generalized lepromata and anaesthesia of the forearms hands and anterior surfaces of the knees legs and feet. When the reaction was tried a local erythematous papule formed in 24 hours increasing in size and developing a red halo in 48 hours persisting for several days and leaving a small pigmented nodule. The patient had an ulcer 12 cm in diameter near the right tendo Achillis biopsy showed the tissue changes of a leishmanial infection but leishmania were not seen. The authors have studied the reaction in 23 leprosy patients and they think it is of possible value in the diagnosis of mixed infections

PEREIRA A. C. *Leprosy of the form clinically inapparent. [Inapparent Leprosy]*
Rev Brasileira Leprologia S Paulo 1945 Dec. v 13 No 4 269-72
 4 figs on 2 pls. [11 refs.]

The case is recorded of a man 20 years of age giving no family history of leprosy who six months earlier had had on the dorsum of each foot raised, symmetrical erythematous lesions which were painful and slightly oedematous. Examination of his nasal mucus revealed the presence of Hansen's bacteria. Within a month the local lesions receded leaving no trace nevertheless the nasal mucus the inguinal gland juice and the lobules of the ears which to all appearances were normal showed the organisms. In spite of there being no clinical evidence of leprosy the man was highly infective and all the more dangerous because of the absence of symptoms he was therefore interned, but escaped soon afterwards.

H Harold Scott

DAVEY T F *Some Observations on the Role of Allergy in Leprosy* *Leprosy*
Review 1946 July v 17 No 2 42-62. [46 refs.]

This is a lengthy discussion which is difficult to summarize of what the author characterizes a hypothetical subject because specific antibodies have not yet been proved in leprosy. Allergy is best seen in the tuberculoid form and similarities with dermal conditions due to the tubercle bacillus are emphasized. The lepra bacillus has feeble pathogenic powers but it can act as an antigen. The early lepromin and the tuberculoid responses are distinct but related indications of the allergic state. In a sensitized tissue an effective concentration of antibody in response to the presence of bacilli is produced at an accelerated rate and some diffusion is probable. The young epithelioid cell is said to be the most effective bacteriological element in the tuberculoid response. The appearance of secondary spreading foci indicates a fall of antibody in the skin caused by a decline in sensitivity. The work of DHARMENDRA and LOWE indicate that the release of bacillary protein on breaking down of the lepra bacilli is a necessary preliminary to the allergic response and a time-lag may be due to the interval required for this to take place. The antibody must be synthesized in the reticulo-endothelial system of the skin this is a local reaction because one tuberculoid macule may resolve while another spreads at its edge. The author concludes that while allergy is not equivalent to immunity a successful allergic response imparts a degree of local immunity as well as destroying the bacillus

SCHUJMAN S. Estudo comparativo entre a reação de Mantoux e a de Mitsuda nas diversas formas clínicas da lepra. [Comparison of the Mantoux and Mitsuda Reactions in Leprosy] *Rev Brasileira Leprologia* S Paulo. 1945 Dec. v 13 No. 4 231-6 English summary

This paper deals with observations upon 210 adult patients suffering from leprosy in the city of Rosario.

The object of the investigation was to compare the results of the Mantoux and Mitsuda reactions in the nodular and the nervous-tuberculoid forms of leprosy respectively.

Initial grouping divided the patients into 122 cases of the nodular type (Mitsuda negative) and 88 of the tuberculoid type (Mitsuda positive).

After performing Mantoux tests on all the patients, the author arrived at the following conclusions —

(1) The percentage of anergy to tuberculin (Mantoux negative 1/10) is higher in the nodular than in the tuberculoid type namely 19 per cent as compared with 3.5 per cent.

(2) The discrepancy arising from the result Mantoux positive and Mitsuda negative is only observed in nodular cases, while in tuberculoid cases, the two tests show agreement to the extent of producing 98 per cent. positive results.

(3) The discrepancy between the Mantoux and Mitsuda reactions in the nodular type of leprosy is explained by the existence of specific anergy to *Mycobacterium leprae* on the part of patients suffering from this type of the disease.

MOVIER R. Aspects différents du bacille de Hansen dans le sang de lepromateux coloré par la méthode de Macchiavella. [Hansen's Bacillus stained with Macchiavella's Method.] *Bull. Soc. Path. Exot.* 1948, v 39 Nos. 5/8 167-70

This method consists first of staining for two and a half minutes with a 0.25 per cent. solution of fuchsin then differentiating by passing the slide very rapidly through a 0.5 per cent. solution of citric acid and finally counterstaining for a few seconds with a 1 per cent. solution of methylene blue. Specimens of the leucocyte layer of citrated blood from a vein of a case of lepromatous leprosy with bundles of lepra bacilli in large monocytes when stained in this way showed large numbers of clear unstained bacilli seen against the blue background of the corpuscles. In addition a very few short bacilli, only one or two per leucocyte, were found stained vivid red as described in another paper by the same author [see the following abstract]. This finding raised some interesting questions regarding the significance of the very numerous unstained and the very few stained bacilli in such specimens. The author suggests that the unstained ones represent the usual form of Hansen's bacillus furnished with a waxy coat which prevents the action of this stain but the few red bacilli are young forms without a waxy coat, which take the stain. The former may not be able to infect but the latter may be the only infective forms. Their rarity might account for the slight degree of contagiousness of leprosy.

MACCHIAVELLA R. Bacillémie lépreuse. Affinités tinctoriales du bacille de Hansen. [Bacillæmia of Leprosy Staining Characters of Hansen's Bacillus.] *Bull. Acad. Méd.* 1948 v 130 Nos. 9/10 & 11 163-8.

In leprosy the presence of the bacilli in blood should be determined by puncturing a vein through unaffected skin. He advises withdrawing 2 to 3 cc. in sodium citrate solution, and centrifuging. Smears should be made from

the layer of leucocytes because the bacilli are nearly always found in bundles in large monocyte cells although a few may be free in the blood stream. By this method positive results nearly always are obtained in generalized lepromatous cases especially during febrile reactions but never in the author's experience in tuberculoid and trophoneurotic cases. On staining the blood preparations by Macchiavello's method faggots of bacilli may be seen unstained in contrast to a few of a deep red colour in the cells [see the preceding abstract] the stained ones are very short. On staining with heated Giemsa for half an hour the few short bacilli stain to a mallow or mauve colour. *L. Rogers*

DE WILDEMAN E. A propos de médicaments antilépreux d'origine végétale
VI Senecio L. [Vegetable Anti-Leprous Drugs] *Inst Roy Colonial Belge—Bull des Séances* 1946 v 17 No 1 317-53

In this long paper the author enumerates 103 species of the genus *Senecio* and the family of Compositae together with notes of the medicinal uses to which they have been put. Alkaloids have been described in a number of them the names of nine of which are given they appear to differ little among themselves and little or nothing seems to be known of their action in the numerous diseases of man and beast for which they have been recommended from time to time. Among the diseases of man referred to are cardiac respiratory liver urinary affections and diseases of the male and female sexual organs. Among general diseases are hysteria, anthrax syphilis and a number of diseases affecting the skin such as ulcers and boils diabetes and leprosy. The only variety mentioned with regard to the last named is *Senecio Kleinia* of the Indies and Canary Islands. The author points out that little is known regarding the precise chemical constituents of these plants some of which are highly toxic. Research is therefore required regarding their true toxic principles and their distribution in different parts of the plants. Until this has been done recommendations as yet made for their uses in medicine must be regarded as preliminary and provisional. The present paper will be useful to anyone undertaking a serious study of the medicinal properties of this genus. *L. Rogers*

[A Contribution to the Treatment of the Leprosy Reaction.] *Rev Brasileira Leprologia* S Paulo 1945 Dec. v 13 No 4 277-9

The author has used pituitrin successfully in the treatment of the leprosy reaction.

SLOAN N. R. Tracheotomy in Leprosy *Hawaii Med J* 1946, Jan.-Feb v 5 No. 3 125-8, 4 figs.

ROGERS L. Progress in the Control of Leprosy in the British Empire *Brit Med. J* 1946 June 1 825-8.

This is a very full extract of a paper read before the Royal Society of Arts (*Roy Soc Arts* 1946 v 94 525) which deals with the general progress during the last three decades of prophylaxis against leprosy. Reference is first made to the introduction of the modified treatment by injection of suitable products of the old Indian remedy chaulmoogra oils with improved results in early cases only. Next epidemiological work to enable a plan to be formulated whereby early cases may be detected by repeated examinations of close contacts of known cases of leprosy with their treatment on a large scale at out patient clinics. In addition it is essential to success in reducing the incidence

of leprosy to provide agricultural leproseries for the admission and treatment of the advanced infective lepromatous cases under a voluntary system as far as possible the old rigid compulsory segregation must also be modified to allow of out patient treatment of early cases which are otherwise hidden. Successful trials of these methods with the help of the British Empire Leprosy Relief Association founded in 1924 are recorded. Only the fringe of the problem has yet been tackled in view of the number of cases of leprosy in the British Empire now estimated at two million but the way has been opened up for extending gradually the use of the modern methods described. L. Rogers.

FIELDING J W Further Observations on Rat Leprosy *Med J Australia* 1946 May 18 v 1 No 20 681-6

Further experiments on rat leprosy are recorded in this paper. Light natural infections with rat leprosy have been found in one *Rattus norvegicus* and in one *R. rattus*. Other rats are reported to have become infected from excreta containing acid fast bacilli in the mud floors of their cages after a few weeks of contact. Moreover continued inoculation with organisms in excreta results in the production of intracellularity of organisms and in lesions but there was no evidence of typical maximum intracellularity similar to that observed in leprotic lesions. It was also found that carbolized organisms were still viable and capable of undermining the resistance of an animal. Immunization was not obtained by injections of carbolized organisms. After removal from contact with infected soil, rats may become free from infection after 72 days. It is also stated that the infection of rats by rat leprosy is not enhanced by vitamin B₂ deficiency. [The claims made in this and the previous paper see this *Bulletin* 1945 v 42, 803 are based on the assumption that the acid fast bacilli found in the excreta of infected human beings and rats are the true causative organisms of leprotic infections.] L. Rogers

HELMINTHIASIS

BADIR G Schistosomiasis of the Conjunctiva. *Brit J Ophthalm* 1946 Apr v 30 No 4 215-21 3 figs. on 2 pls.

Schistosomiasis of the conjunctiva is reviewed by Badir and he describes a case which is unique in that it is the first one reported where the worms were observed *in situ* under the conjunctiva. The patient was a boy aged 12 years on examination a tumour of the palpebral conjunctiva of the left upper eyelid was found near the inner canthus. The tumour had been present for more than a month. The swelling was excised and the specimen on examination showed a large number of terminal-spined bilharzia ova [presumably *S. haematobium*]. Many of the ova were degenerated. A male and an included female bilharzia worm were seen lying in a dilated orbital vein.

E O G KIRWAN

KAMEL A Schistosomiasis (Bilharziasis) of the Conjunctiva. *14th Rep Memorial Ophthalmic Laboratory Giza Cairo for 1939-1944* 118-23

In spite of the fact that Egypt is highly infested with bilharzia and that bilharzial granulomata have been found in nearly every part of the body yet bilharzial lesions of the eye are very rare. The ova reach the conjunctiva probably during the migration of young worms some to reach their goal probably wander the wrong way into the vessels of the head to find themselves

in the vicinity of the mucous membrane of the conjunctiva, where they deposit their ova. The ova deposited in the submucosa are seen to be surrounded by an area of digestive rarefaction produced by digestive enzymes secreted by the lateral glands of the embryo. To this zone of rarefaction leucocytes migrate and the eosinophil cells are the most prominent. This is what is called schistosomiasis pseudo-abscess and differs from the ordinary pyogenic abscess in that it does not suppurate.

The lesions may be seen in the conjunctiva as (1) small yellowish pink nodules on the bulbar conjunctiva, single or multiple surrounded by leashes of small vessels and bearing great resemblance to streptothrix nodules of the conjunctiva. (2) polypoid masses arising from the fornices. (3) chalazion-like granulomata on the tarsal conjunctiva. In all forms however one can easily recognize yellowish dots in the centre, not unlike the post trachomatous degenerations of trachoma and if one ruptures and spreads the contents of such nodules on a slide ova can be found by direct examination under the microscope. The lesions are not painful and the patient's attention is usually attracted by the disfigurement. Unlike tuberculosis the preauricular and submaxillary glands are not enlarged in schistosomiasis of the conjunctiva.

One case was seen in which the lesion was bilateral, and cases have been reported from Upper as well as from Lower Egypt. E O G KIRWAN

FLOCH H & DE LAJUDIE P. Sur les bilharzioses en Guyane française. [Schistosomiasis in French Guiana.] *Institut Pasteur de la Guyane et du Territoire de l'Inini* Publication No 119 1945 Dec. 5 pp [14 refs.]

The authors make the point that most if not all of the few cases of *S. mansoni* infection which have been reported from French Guiana have been acquired outside that country. This infection is endemic in the Antilles, Venezuela, British and Dutch Guiana and elsewhere. *S. haematobium* infection, on the other hand, is not endemic anywhere in the Americas and only imported cases have been seen. Schistosomiasis is not therefore an important disease in French Guiana and the authors have failed to find the common American mollusc host *Australorbis glabratus*. Charles Wilcocks

WELLER T H & DAMMIN G J. The Incidence and Distribution of *Schistosoma mansoni* and other Helminths in Puerto Rico. *Puerto Rico J Pub Health & Trop Med* 1945 Dec. v 21 No 2 125-47 6 figs. [Refs in footnotes.] [Spanish version 148-65.]

A single stool specimen from each of 19 139 Puerto Rican Selective Service registrants was examined for helminth eggs and larvae by a modification of the Telemann acid-ether centrifugation technique. While the group studied was not representative of the total adult male population these findings comprise the first available data on a relatively uniform group of individuals drawn from all sections of the Island.

Helminth eggs and larvae were found as follows. *Schistosoma mansoni* in 1.909 or 9.97 per cent. Hookworm in 10 822, or 56.5 per cent. *Ascaris lumbricoides* in 1.288 or 6.7 per cent. *Trichuris trichiura* in 14 614 or 76.3 per cent. *Strongyloides stercoralis* in 1.984 or 10.4 per cent. *Hymenolepis nana* in 29 or 0.15 per cent. and *Taenia* sp. in 5 or 0.03 per cent. The helminth index was 1.6

The data were analyzed to obtain information on the relationship of the occurrence of the five common parasites to the age and geographical and occupational distribution of the selectees.

BARROS, J. de R. Determinações nervosas da parasitose sanguínea de Manson e Pirajá da Silva. Forma epiléptica. [Nervous Symptoms in Infestation by *Schistosoma mansoni*.] *Publicações Médicas* São Paulo 1946 Feb v 17 No 7 (199) 43-45-8.

The author states that *Schistosoma mansoni* may give rise to symptoms of involvement of the nervous system varying from general irritability to attacks of vertigo and actual epileptic seizures. He has notes of "some thirty such cases" and gives details of one. The patient was a man of 29 years, seen by the author in 1937. He had had three attacks of malaria since the age of 12 but was generally healthy and strong. There was no evidence of any venereal disease, nevertheless his attacks of abdominal and sacro-lumbar pain, occasional passage of stools with mucus and streaks of blood, vertigo and nocturnal epileptic seizures with loss of consciousness were ascribed to syphilis and he was given antisyphilitic treatment but without any benefit. Examination of the faeces showed cysts of amoeba coli and ova of ankylostomes and of *Sch. mansoni*. After a course of thymol and of foudadm, he had no more vertigo or epileptiform attacks and he has remained well. He was last examined in 1945 8½ years after coming under the author's observation.

H. Harold Scott

HERNÁNDEZ MORALES F. & OLIVER GONZÁLEZ, J. Ova of *Schistosoma mansoni* in Purged and Unpurged Faecal Specimens. *Puerto Rico J Pub Health & Trop Med* 1945 Dec. v 21 No 2 209-10 [Spanish version 211-12.]

The authors examined the purged and unpurged faecal specimens of 120 persons, found to harbour *S. mansoni* ova in their stools after a dose of magnesium sulphate. The first faecal samples when no purge had been given, revealed that ova could only be found in 59.3 per cent. of the patients. It is concluded that the ova of this parasite may be found more readily after the administration of a purgative.

TORRES, C. M. & PINTO, C. Lesões produzidas pelo "*Schistosoma mansoni*" no tatu (*Euphractus sexinctus*) mecanismo de eliminação dos ovos e sensibilidade da espécie animal nas infestações experimentais. [Lesions produced by *S. mansoni* in the Armadillo. Mechanism of Elimination of Eggs. Susceptibility of the Armadillo to Experimental Infection.] *Mem Inst. Oswaldo Cruz* 1945 Oct., v 43 No 2 301-48, 38 figs. (3 coloured) [23 refs.] [Summary in English by the authors.]

* 1 The post-mortem examination of a male armadillo (*Euphractus sexinctus*) experimentally infected by *Schistosoma mansoni* has shown 88 adult female worms and 23 male worms inside the liver and 4 (2 male and 2 female worms) inside the pancreas.

Ova of *S. mansoni* were found in the faeces since the 53rd day after infection persisting till the death of the animal 41 days later.

Schistosomal pseudotubercles are very numerous in the small and large intestine, in the liver and haemolymph nodes. They could not be detected in the lungs, pancreas, heart-muscle, lymph-nodes, kidneys, bladder and testes.

2. Neither cirrhosis of the liver nor polypoid endarteritis and endophlebitis could be demonstrated.

3 In the small intestine ova and schistosomal pseudotubercles remained strictly localized in the submucosa, and none of them was found above the *muscularis mucosae* (i.e. in the mucous coat itself). The small intestine therefore was not related in this particular animal to the elimination of the *S. mansoni* eggs at least at the time in which the post-mortem examination was performed.

4 In the large intestine on the contrary ova and schistosomal pseudotubercles were very numerous in the mucous coat itself and this portion of the gastro-intestinal tract was actually concerned with a very active and widespread liberation of *S. mansoni* eggs.

5 The chief factors affecting the liberation of *S. mansoni* ova as observed in this armadillo are in our opinion (1)—the structure of the large intestine provided with a less regular *muscularis mucosae* as compared with that of the small intestine and larger blood vessels which enter the mucous coat (2)—the extrusion of eggs in the capillaries according to the manner evidenced by KOPFISCH (1937) and their transient fixation in the mucous coat (3)—the formation of a cellular infiltrate about the extruded ova (4)—the histolysis of this cellular infiltrate as well as of the surrounding tissue (5)—disintegration of the walls of the adjoining Lieberkühn's glands as the histolysis increases and consecutive transfer of the eggs to the Lieberkühn's crypt (6)—their further elimination in conjunction with the intestinal juice secreted by the glands.

6 In the small intestine there is an acute catarrhal enteritis probably incited by bacteria or by toxic substances besides a chronic enteritis associated with schistosomal pseudotubercles and eggs.

7 In the large intestine there is a chronic catarrhal colitis associated with schistosomal pseudotubercles and ova, as well as early stages in the development of mucous polyps.

[For another note on the same subject by the same authors see this *Bulletin* 1946 v 43 658.]

MASON P. K., DANIELS W. B., PADDOCK F. K. & GORDON H. H. Schistosomiasis Japonica. Diagnosis and Treatment in American Soldiers. *New England J. of Med.* 1946 Aug 8 v 235 No 6 179-82. [10 refs.]

Four hundred and eighty-one cases of schistosomiasis japonica acquired on Leyte an island in the Philippines were studied at an Army general hospital in the United States.

Recurrent epigastric cramps and tenderness were the most frequent complaints on admission but in almost all cases these had disappeared by the time of discharge.

Repeated stool examinations by more than one method were necessary to demonstrate the eggs of *Schistosoma japonicum*. A persistent eosinophilia was suggestive but not diagnostic of continued activity of the disease.

On the basis of comparable series treatment with tartar emetic was found to be much more effective than that with fuadin. Significant toxic reactions with tartar emetic were rare.

It is urged that stool examinations be done repeatedly and by multiple methods on men who have been exposed to this disease so that treatment may be instituted if ova are found.

TUCKER, H. A. Intestinal Cestode Infections in Natives of Panama. *Puerto Rico J Pub Health & Trop Med* 1946 June v 21 No 4 384-5. [Spanish version 366-8.]

1 In a review of 558,566 admissions to Gorgas Hospital Ancon Canal Zone from May 1904 to November 1944 128 instances of intestinal cestode infections were found. Only 15 of these were unquestionably autochthonous in origin

2 The paucity of suitable intermediate hosts together with inspection and thorough cooking of meats were considered the most important factors in explaining this low incidence

3 All parasites found were generally accepted as being cosmopolitan in distribution only 3 species could be definitely considered of local origin—*Taenia saginata* *Taenia solium* and *Hymenolepis nana*

DA SILVA, P. B. Estrongiloidase. Sintomatologia e tratamento [Strongyloidosis. Symptoms and Treatment.] *Publicações Médicas* São Paulo 1946 Feb. v 17 No 7 (159) 49 51-2.

In 1937 the author had occasion to pass a duodenal tube on a man 23 years of age with signs of duodenal ulcer and he found in the bile and duodenal material abstracted a large number of ova and larvae of *Strongyloides stercoralis*. He was accustomed to treat gastric and duodenal ulcers by daily lavage with 0.1 per cent gentian violet and gave that treatment to this patient. At the end of a week no more worms were seen and the patient felt well.

Some days later a girl of 11 years was seen suffering from severe anaemia and obstinate diarrhoea—the faeces contained larvae of *Strongyloides* in large numbers. She objected to the passage of a duodenal tube so the gentian violet was given twice daily in capsules each containing 0.025 gm. for 10 consecutive days. The diarrhoea ceased and the anaemia had improved and examination of the stools failed to reveal any worms. A brother of the last, aged 8 years similarly affected, was cured in the same length of time.

In his conclusions the author states that infestation by *Strongyloides stercoralis* is fairly common in Rio State—in the course of about 2 000 duodenal intubations he has met with an average of 30 per cent. infested—that the best results in treatment are attained by the introduction of 20 cc. of a 0.1 per cent. solution of gentian violet by means of a duodenal tube, or by capsules of 0.025 gm. of the drug twice a day. If the patient complains of giddiness or malaise after taking the drug it should be given after the chief meals of the day.

PACHECO-LUNA, R. Notes on Onchocerciasis in Guatemala. *Brit J Ophthalm* 1946 Apr 30 No 4 234-7 [19 refs]

[The author spells Onchocerciasis Onchocerciasis throughout] Onchocerciasis in Guatemala is described by Pacheco-Luna. It was discovered there in 1915 by ROBLES and is endemic principally in regions devoted to the production of coffee and situated at altitudes of 300 to 1,200 metres on the steep slopes of the Sierra Madre. It is estimated that 20 000 persons are infected. Ocular manifestations are observed in 30 per cent. of these and 2 per cent. are blind. The signs of onchocerciasis are classified under three heads—the tumours the characteristic ocular signs which sometimes end in blindness and some rare cutaneous manifestations. The ocular changes are due to a chronic slow and insidious process of sclerosis which takes years to develop. It is caused by the presence of the microfilariae alive or dead, in the tissues of the eye and by the secretions and excretions of both microfilariae and filariae. These act both locally and at a distance possibly by means of toxic products of protein disintegration. The early symptoms are severe photophobia blepharospasm and a sensation of a foreign body in the eye. At first only a slight ciliary injection is visible but with the corneal microscope a superficial punctate keratitis can be seen. This affects the ends of the horizontal diameter leaving the centre of the cornea free. Later the infiltrations invade the deeper tissues. In some cases whilst the keratitis is in progress but in others independently a plastic iritis develops which seriously affects vision. At first the pupil is contracted. Synechiae and pseudo-membranes develop which obstruct the pupil and force it downwards giving it a pear-shape. The process extends to the uveal tract and degenerated pigmentary lesions of the choroid and retina have been observed. Examination of them is difficult owing to the clouding of the vitreous. In advanced cases the ocular tension is low and the process ends by *phthisis bulbi*. Unfortunately up to the present no therapeutic agent has been found which acts with good results upon the parasites

E O G KIRWAN

DEFICIENCY DISEASES.

CRICKSHANK E. K. Painful Feet in Prisoners-of-War in the Far East. Review of 500 Cases. *Lancet* 1946 Sept 14 369-72, 2 figs

The author saw 500 cases of this syndrome among British and Australian prisoners in Changi Camp Singapore. It appeared after six months of captivity during which the prisoners had received a diet supplying adequate calories but deficient in first-class protein and in the B group of vitamins. Fresh cases ceased to appear in any numbers and the sufferers gradually recovered, after a few months when there was an all-round improvement in the diet although the quantity of riboflavin supplied remained low. The greatest incidence of painful feet occurred at a time when fresh cases of recognized thiamin deficiency were relatively few.

two important deviations from this were encountered *viz.*—(1) Many stools with a high fat content were well pigmented and not unduly bulky—an observation previously noted [Black and Fourman, this *Bulletin* 1948 v 43 474] further on exposure to light and air pale stools darken in colour and (2) many patients with sprue suffer from attacks of watery diarrhoea (clinical dysentery). The lack of pigmentation in the sprue stool is usually held to be due to the reduction of stercobilin to stercobilinogen but simple dilution of the pigment by fat may be contributory to it. The dysenteric diarrhoea may be due to an intercurrent bacillary dysenteric infection in which case it responds to sulphaguanidine treatment but possibly more often, sulphonamide-susceptible organisms normally commensal become pathogenic in an abnormal gut. Such diarrhoea was observed to yield promptly to parenterally-administered liver extract.

The ratio of split to unsplit fat in sprue usually exceeds the normal 3:1 or 4:1 and this has been attributed to defective absorption of split as opposed to unsplit fat. Bloor (*Biochemistry of the Fatty Acids* New York, 1943) found that normal stools can partially break down neutral fat added to them: the authors find that this lipolytic property is possessed in even greater degree by sprue stools, probably because of the emulsifying action of their high soap content. The lipolytic action was not arrested by penicillin or sulphathiazole, so is not bacterial in origin: it was lessened by the addition of 5 per cent copper sulphate. The relative absorptions of split and of unsplit fats in sprue, therefore cannot be deduced from an analysis of the stools.

The ratios of total split fat and of split fat in the form of soaps in 46 dried stools from ten patients are set out in tabular form. In all but six of these the ratio of split fat present as soaps was found to be over 60 per cent. irrespective of the total split fat content. Those stools with the greatest content of split fat and containing the greatest amount of soluble soap were the most alkaline—which suggests that the irritant nature of very fatty stools is due to a high content of soluble soaps and not to acidity.

The non-fat dry residue (N.F.D.R.) is composed largely of bacteria and of unabsorbed food residue. On a controlled diet this residue should remain constant but the authors found that after treatment of many but not all of their sprue cases with liver and yeast-extract the N.F.D.R. diminished. The cause of this was not determined but such a diminution in this residue may mask a decrease in the gross fat excretion, the percentage figure for fat in the dried stool as a result of it being unaltered.

With gross variations in steatorrhoea, such as occur in sprue under treatment a fair measure of the water content of the stool cannot be determined by the ratio of dry to wet stool weight: the fatty part of the stool not being wetted. A percentage water content has been calculated from wet weight of stool minus fat and dry weight of stool minus fat, and average figures for 68 stools from 11 patients are given: stools of higher fat content were found to have a higher percentage of water.

In mild or atypical sprue the percentage of fat in the dried stool may be normal, especially if the patient is restricting his fat intake. To demonstrate steatorrhoea such patients must be put on a diet containing 90–100 gm. of fat daily and the stools collected for at least 24 hours and preferably for four days. The fat excreted on such a diet should not exceed 10 gm. daily in a normal person. Where facilities for collecting and weighing stools are lacking, a percentage of estimation of fat in a mixed 24-hour specimen is of more value than an observation on one stool, and a high residue diet must be avoided so as not to mask minor degrees of steatorrhoea. For accurate observations on fat excretion, twelve-day periods of observation are a minimum requisite.

A. R. D. Adams

FRANDSEN S & KRINGELBACH J *Investigations in the Behaviour of the Serum Iron in Hyperchromic Sprue Anemia. Acta Med Scandinavica* 1946 v 125 No 1 29-39 2 figs [10 refs]

By the term sprue in this article the form more generally known as idiopathic steatorrhoea is probably indicated

Two cases of untreated hyperchromic anaemia in sprue which were investigated immediately after injections of liver showed a reduction of the serum iron value from high normal values to low subnormal values as well as a tendency to persistent low values during continued treatment. The curve thus obtained corresponds to that usually observed in the serum iron of pernicious anaemia during the course of similar treatment. In the first during a reticulocyte rise the peak was reached just after a decrease of the serum iron content had been noted. In the second case decrease in serum iron was more protracted.

In these instances where similarity of the behaviour of serum-iron during the liver treatment of hyperchromic sprue anaemia and that of pernicious anaemia is observed a certain parallelism is to be expected. It appears that no prediction as to the eventual response of the anaemia to specific treatment can be made from the behaviour of the serum iron. In these two cases as a result of treatment the serum-iron fell from normal (high) values—152-170 γ per cent and 173-152 γ per cent to subnormal values—68 γ per cent and 37 γ per cent.—respectively analogous to the conditions observed in pernicious anaemia.

P Manson-Bahr

WINGFIELD A L *Some Observations on the Aetiology and Treatment of Sprue Proc Roy Soc Med* 1946 July v 39 No 9 519-22 (Sect of Med. 15-18) 2 figs. [14 refs]

The author believes that the very rapid response to treatment points to a disorder of function rather than of structure as the basis of sprue. Since 1939 he has made it his practice to permit all patients with sprue to partake of full ward diet and to get up when they wish. They are treated with crude liver injections (Plexan) 4 cc. daily for one week, then on alternate days for one week and twice weekly thereafter and to this is added nicotinic acid 50 mgm three times daily.

A single dose of nicotinic acid 150 mgs is given to test vasomotor and digestive reactions. So far no patient tested has complained of flushing before the beginning of treatments while all patients have given a specific vasomotor response after treatment for two to three weeks. This observation supports the contention that crude liver quickly restores intestinal function. Nine patients were treated on these lines with satisfactory response the average gain in weight has been 27 pounds varying from 13-32 pounds. Stools return to normal in about seven days. Untoward phenomena have been pain at site of injection and transient oedema of the legs and feet has occurred in the second week possibly because of sodium retention.

One extreme case is cited the patient on this mode of treatment doubled her weight.

His experiences have led the author to believe that diet is of little or no consequence in the treatment of sprue. Crude liver extract is important possibly because it is a potent source of vitamin B₁₂ complex, but it also contains an unidentified fraction which may prove to be the specific factor

P Manson-Bahr

penicillin in a strength of 6 units per cubic centimeter. Treatment was instituted with an ointment containing 5 000 units of penicillin per gram and complete involution occurred after two weeks of therapy. Treatment was then continued for another two weeks to insure permanency of results.

The last patient in this group had been hospitalized almost continuously for the preceding eight months because of a treatment resistant syccosis vulgaris. Three million units of penicillin had been administered intramuscularly in eight separate courses and penicillin ointment had been used for three weeks without affecting any improvement. On culture a coagulase-positive hemolytic *Staph aureus* was found, with sensitivity to penicillin in a strength of 20 units per cubic centimeter. Penicillin ointment in a strength of 100 000 units per gram was used and cure was accomplished with three days of therapy. In all treatment was continued for five days and there was not the slightest evidence of local irritation. The patient was followed for another month, but relapse did not occur.

Despite these successes, failures were recorded in other cases, although in some instances penicillin ointment containing 3,330 units per gramme was used, and in one case the ointment was loaded with 10 000 units per gramme. Therefore the authors conclude that even massive penicillin therapy may be inadequate, and may lead to the development of increased penicillin resistance.

Cornu and Alsever consider that the only obvious indication for the administration of penicillin intramuscularly is in cases of severe, widespread infectious eczematoid dermatitis.

In the treatment of 10 patients suffering from pyoderma, sulphadiazine (5 per cent.) was added to penicillin ointment of standard strength (500 units per gramme) the results were disappointing. However benefit did seem to accrue in four patients who received two courses of penicillin locally with an intervening oral course of sulphadiazine.

As the study progressed the filter paper method of bacteriological assessment was given up and the authors adopted, as more accurate a method of assessment devised by COOKE [*Bulletin of Hygiene* 1945 v 20 497] in which penicillin solutions of varying strength and measured amount (0.1 cc.) are applied evenly to the agar and dried quickly in the refrigerator the organisms to be tested are then streaked across the area and the inhibition of growth, or its absence noted as usual.

As a result of their studies they suggest the following scheme of correlation between the strength of penicillin ointment and the sensitivity of the organisms concerned —

Strength of penicillin ointment to be used in treatment according to sensitivity of organisms to penicillin

Sensitivity of Organism		Strength of penicillin units per gramme of ointment
Filter paper method units per cc	Cooke method, units per 0.1 cc.	
1	0.03 to 0.06	500
2	0.1	1 000
4	0.15	3 000
6	0.2	5 000
8	0.25	7,500
10 to 20	0.3 to 0.6	10 000 to 25 000 (?)
20 to 30	0.6 to 1	25 000 to 50 000 (?)
30 to 50	1 to 2	100 000 (?)

R. M. B. MacLEOD.

JACKSON W P U Plant Dermatitis in the Bahamas. [Memoranda.] *Brit Med J* 1946 Aug 31 298

The shrub *Metopium toxiferum* (family Spondiaceae) known as poison wood or poison bark contains a toxin at least as powerful as that of *Rhus toxicodendron*. It flourishes throughout the open spaces of the Bahamas and Southern Florida. The toxin is present in the milk beneath the bark in the leaves and in the fruit and tends to ooze to the surface of bark and leaves producing black stains.

After contact of the skin with this toxic resin there are usually no symptoms for a few days but thereafter small papules are formed which rapidly become vesicular there is itching and surrounding erythema and the lesions usually ulcerate. The rash may spread to distant parts of the body probably as a result of a general allergic reaction of systemic dissemination since blister fluid is not toxic and finger-spread is therefore not likely. The whole process may continue for several weeks. Sometimes the rash is more urticarial with gross erythema and oedema. One drop of the fluid may produce a widespread rash.

Charles Wilcocks

SANTON W J HATCHER F & DERRICK, E. H. Chromoblastomycosis, with Reports of Two Cases occurring in Queensland. *Med J Australia* 1946 May 18 v 1 No 20 695-7 6 figs on 1 pl

Chromomycosis or mossy foot although found in many parts of the world is not common in any country. The authors describe two cases the first to be reported in Australia. In both cases the lesion was a small painless non-inflammatory plaque about 15 mm in diameter with a flattened surface elevated a few millimetres above the level of the surrounding healthy skin. On one patient the lesion which had evolved from a small wart like papule was of 7 years duration and on the other a matter of only 5 months. Topical treatment proved ineffective and excision was practised in both cases. Histologically the lesion was a cutaneous granuloma composed of histiocytes and plasma cells with polymorphonuclear and mononuclear leucocytes numerous giant cells of the foreign-body type and many very conspicuous eosinophil cells. The fibroblastic reaction was very slight but there were marked epidermal proliferations which in neglected cases give rise to the papillomatous character of the lesions. The fungal parasite was seen singly or in little groups scattered throughout the tissue often within giant cells or forming the central object of a little abscess of polymorphonuclear cells. The fungal cells were round or oval from 5 μ to 14 μ in diameter averaging 8 to 10 μ they were of a brown colour thick walled and in some cases septate. Unfortunately the tissues were fixed in formol before the diagnosis was made so the identification of the fungus by culture was not possible.

J T Duncan

PARÁ, M. Histoplasmosis in Brazil. *Amer J Trop Med* 1946 May v 26 No 3 273-82 17 figs [36 refs.]

The author who is a member of the National Yellow Fever Service of Brazil diagnosed five cases of histoplasmosis in the routine histological examination of 169,808 viscerotomy specimens collected in connexion with the yellow fever survey during the period 1939 to 1945. As the diagnoses were made some time after death confirmation by cultivation of the fungus was not possible and the case histories obtained were incomplete. All five patients were children, 2 boys and 3 girls between the ages of 19 months and 9 years. The cases occurred in the following districts: Recreio Minas Gerais, Vinífrica São Paulo, João Alfredo Pernambuco and Itapé Bahia (2 cases). Four were diagnosed.

In the causation of blindness in all age groups, conjunctivitis and its complications were responsible for 103 out of 234 cases, smallpox for 103, cataract for 28 and glaucoma for 10 cases. Many cases of severe conjunctivitis showed evidence of keratomalacia, a condition which is also very prevalent. [No mention is made of trachoma as a cause of blindness.]

It is believed that at least 80 per cent. of the cases of blindness could be prevented by widespread compulsory vaccination by the provision of a more suitable dietary containing vitamin A and by extending medical facilities in order to ensure that all cases of conjunctivitis should receive adequate treatment.

Trachoma—During the past eighteen years Wilson⁵ has had a unique opportunity of studying trachoma from many varied angles and in this article he reviews certain personal observations made during that period. In discussing the aetiology of the disease he states no one has yet succeeded in isolating the infective agent of trachoma in pure culture but there is no doubt that it is a specific infection. He rejects the theories of a lymphatic dyscrasia, adenoidism, nutritional deficiency or similar concepts and does not consider these factors to be predisposing causes.

He regards the evidence in favour of a rickettsia as a cause of trachoma to be far from convincing. *Bacterium granulosis* he regards as the cause not of trachoma, but of a simple form of chronic granular conjunctivitis. He is convinced that typical intracellular inclusion bodies are invariably present in the incipient stages of trachoma and also that, if they are not demonstrable in the early stages of any disease under examination, the disease present is not trachoma. In this connexion it is to be observed that inclusions may be found in the trachomatous conjunctival epithelium some appreciable time before characteristic clinical signs appear in the tarsal conjunctiva but as the disease progresses they rapidly decrease in number and the chances of finding them are correspondingly diminished after the first three months from onset. Therefore while the demonstration of the inclusions in the earliest stages of any doubtful case is of the utmost significance their absence in the later stages is, from the diagnostic point of view of little importance. There is no doubt now that trachoma is caused by a filterable virus and that the specific infectious agent is demonstrable as an intracellular inclusion body identical with the chlamydozoa originally described by PROWAZEK and HALBERSTADTER.

Wilson discusses the problem of animal experimentation and is of opinion that the ideal experimental animal for trachoma has yet to be found. It would appear that the Sudanese monkey (*grivet* or *Leopitryga griseocervicalis*) is the most susceptible of all the monkeys and apes. When such animals are directly inoculated with trachoma material, mild conjunctival congestion and follicles begin to appear in the upper fornices after a fortnight or so, and sometimes quite a considerable crop of follicles may appear but these gradually retrogress and may perhaps entirely disappear after several months. Appearance of T1 follicles on the tarsi has never been observed, nor does scarring of the conjunctiva or vascularization of the cornea ever take place. Furthermore intracellular inclusions are not found. The position is even more complicated since monkeys may also suffer from a form of spontaneous folliculosis of varying severity which is indistinguishable clinically from the disease produced by the inoculation of trachomatous material and in this disease also intracellular inclusions are not found. BLAND⁶ has shown that trachoma can definitely be

⁵WILSON, R. P. Trachoma. A Selection of Personal Observations and Experiences. 11th Rep. Memorial Ophthalmic Laboratory Giza, Cairo for 1939-1941. 15-57. [16 refs.]

⁶BLAND, J. O. W. The Aetiology of Trachoma. A Critical Review of Present Knowledge. 16th Rep. Memorial Ophthalmic Laboratory Giza, Cairo for 1939-1944. 80-108. [58 refs.]

passed from monkey to monkey through man producing all the pathognomonic lesions of the disease and back again to the monkey spontaneous folliculosis is not transmissible in this way. When human trachoma is transferred to the human conjunctiva typical lesions of the human disease are developed and Prowazek Halberstaedter inclusion bodies are present in abundance. Thus the virus of trachoma although not demonstrable in the conjunctival epithelium of the monkey nevertheless rapidly develops and produces typical colonies after transfer to the human conjunctiva.

In Egypt trachoma is not in the true sense of the word epidemic it is pandemic. It makes its appearance at all times of the year and may be found in 100 per cent of the village population and only to a slightly less degree in the big towns. The disease develops in children before they are a year old and is invariably preceded by a Koch Weeks conjunctivitis. The usual interval which elapses between the onset of an acute muco-purulent conjunctivitis and the first definite clinical signs of trachoma varies from 6-12 weeks. The virus of trachoma is carried across from eye to eye by flies at the same time as the acute bacterial infection. Fingers are not important in dissemination (but compare SCHNEIDER, above). The influence of climate temperature altitude geographical distribution dust racial predisposition and the like is in no way causal but merely concomitant. Bad hygienic conditions are also only predisposing factors. If the fly scourge in Egypt could be controlled effectively there would be a spectacular and immediate radical change in the incidence of trachoma and acute ophthalmia alike.

Egyptians suffering from trachoma react very differently from Europeans for the tendency towards spontaneous cure is much more evident among the former. This is due probably to a relative degree of inherited immunity rather than to attenuation of virus. The contagiousness of trachoma is not nearly so high as it has always been considered to be except perhaps in the earliest stages when there is a certain amount of active secretion from the eyes. The superposition of an acute or chronic bacterial infection which thus produces an increased quantity of infective material available for the dissemination of the disease is the factor which most enhances the contagiousness of the disease.

Formerly T1 follicles were regarded as the principal pathognomonic sign of trachoma, but more recent research has proved that there are certain other signs just as pathognomonic. These are not to be looked for in the palpebral conjunctiva, but on the globe. From the 5th-7th day after infection, during the incipient stage of the disease a narrow band of raised limbal oedema, skirting the upper half of the cornea and tailing away in the lower half gradually makes its appearance. It is due to commencing infection of this part of the eye for examination with a corneal loupe or a slit lamp inspection of the limbus shows all the characteristic signs of superficial corneal invasion i.e. engorgement of limbal vessels superficial limbal corneal infiltrations extension of the end capillary loops into the cornea etc. Very soon after the cornea begins to show definite signs of invasion this limbal band of oedema becomes obscured as the mild oedema becomes more generalized.

In the differential diagnosis of follicular conjunctivitis and chronic conjunctivitis from trachoma the absence of invasive signs in the limbus is a certain proof that the disease is not trachoma and if the condition is of short duration an epithelial scraping is of considerable value for inclusions can almost certainly be found if the disease is trachomatous. If one of these diseases is superimposed upon an old trachoma, then it may be impossible to decide upon the true condition. Under the circumstances it is always rational to treat the element of mixed infection first.

Prophylaxis against trachoma in Egypt has been disappointing and so far has only been of benefit in delaying the onset of the disease a little for many

years to come little amelioration can be expected unless some epoch-making medicament is discovered which will effectively control and prevent the disease. The sulphonamides (sulphapyridine sulphathiazole and sulphadiazine) have proved disappointing in the treatment of trachoma but, on the other hand these drugs have proved so highly and so rapidly effective in the treatment of the acute ophthalmias that provided they are given early it is within the bounds of possibility that they may be capable not only of controlling the regular seasonal epidemics of these acute diseases but also indirectly of reducing very considerably the incidence of trachoma at the same time.

The aetiology of trachoma is also discussed by Bland. At present only two theories are generally accepted, the virus theory and the rickettsial theory. The conflict is indeed one of nomenclature rather than of fact and largely depends upon what we choose to call a rickettsia, and what we call a virus. The evidence so far accumulated leads to the conclusion that trachoma is a specific infectious disease not caused by any culturable bacterium, but due to a filter-passing agent which is identical with the elementary and initial forms found in the inclusion bodies (Prowazek Halberstaedter inclusions) and bearing a close natural relationship to the viruses of inclusion conjunctivitis, lymphogranuloma inguinale and psittacosis. There is no evidence that this agent possesses an arthropod host nor that the louse is the vector of the disease, though the agent may survive for some days in the body of the louse. Bland considers that these four agents stand in an intermediate position between the rickettsiae and the large viruses, and may possibly form a biological link between them. For the present he would prefer to group them with the viruses but to give them a distinctive position as the "basophilic viruses" on account of the blue staining of their initial bodies and of the matrix of their inclusions which distinguish them from the larger typical viruses which do not possess blue initial bodies and whose inclusions are acidophilic.

The bacteriological and clinical observations on the treatment of the acute ophthalmias of Egypt (i.e. those due to the Koch-Weeks bacillus and the gonococcus) with sulphonamides and penicillin are discussed by BLAND and WILSON.⁵ The untreated case of acute ophthalmia discharges living and virulent organisms from the eyes for at least 8 days, during the whole of which period the patient is a source of infection for others. By sulphonamide treatment, this period can be reduced to perhaps 1 or 2 days for any case will be rendered non-infective 12 hours after the first administration of the drug and after 2 doses of the drug in every case the conjunctival discharge will be bacteriologically negative for at least the whole of the day following the 2 doses, even in the cases that relapse.

The authors found that sulphapyridine sulphathiazole and sulphadiazine are all efficacious but as sulphadiazine is the least toxic it is likely to be the drug of choice. The calculation of dosage according to body weight is not always convenient or practical, and they suggest a dosage based on age the following figures serving as a guide (one tablet contains half a gm.) —

0-3 months	1	tablet twice daily
3-6	1	" "
6-12	1	" "
1 year	1	" "
3 years	1	" "

BLAND J. O. W. & WILSON R. P. Bacteriological and Clinical Observations on the Treatment of the Acute Ophthalmias of Egypt with Sulphonamides and Penicillin. 14th Rep. Memorial Ophthalmic Laboratory Case Cases for 1939-1944 49-71 (70 refs.)

The best way in which to give the drug is to suspend the dose in 2-3 cc of milk and drop it into the child's mouth with an eye dropper. An alternative is to make the dose up into a paste with milk or water and to insert it into the child's mouth on the end of a finger. The authors consider that penicillin is quite unsuitable for the treatment of the acute ophthalmias certainly in Egypt if administered intramuscularly in the form of eye drops for it would impose an enormous strain on the nursing staff and furthermore the Koch-Weeks bacillus is not sensitive to penicillin. Acute ophthalmia is the cause of 80 per cent of the blindness of Egypt and leaves behind in addition a multitude of more or less serious ocular defects. The increased ocular secretion caused by the disease promotes also the spread of trachoma, that second universal plague of Egypt itself a fertile source of damaged sight. No treatment which requires hospitalization or even attendance at hospital no treatment which cannot be taken to the villages where the great majority of the people live and there simply and easily administered can hope to do more than scratch the surface of this problem. The treatment with sulphonamides completely satisfies the conditions. It is simple safe effective and could be given by unqualified persons with a minimum of training. It provides the necessary solution not only for Egypt but also for other tropical countries where similar conditions of life and disease prevail.

Phlyctenular Ophthalmia in Adults is reviewed by SHAH⁶. A series of 484 cases were examined in the eye out patient department of St Mary's Hospital Lahore. Of these patients 138 (28.9 per cent) were over 20 years of age. In this series males comprised 66.6 per cent and females 33.3 per cent. This is at variance with the widely-held view that the disease is one of childhood and early adolescence and that girls are more affected than boys. Apart from these variations in the age and sex distribution there does not appear to be any other significant difference in the clinical signs and symptoms between the disease in adults and in children. The author's findings agree with those of WANG in Shanghai.

Epidemic Kerato-conjunctivitis associated with Skin Lesions is discussed by O'DONOVAN and MICHAELSON⁷. 33 cases were seen. In all cases the scalp or face was affected and there was a strong tendency for the skin and eye lesions to be ipsilateral. In the majority the onset of the skin lesion preceded that of the ocular lesion by a definite but short interval of time. It would appear that lesions of the face and scalp especially those of a seborrhoeic nature may be conducive in some patients to the development of a kerato-conjunctivitis identical with the virus kerato-conjunctivitis occurring in epidemic form. The kerato-conjunctivitis in patients with lesions of the skin is rather more intense as indicated by the greater number with bilateral involvement, adenopathy and deep corneal spread as well as by the slightly longer duration. It is possible that the virus of epidemic kerato-conjunctivitis can possess dermatotropic qualities as do the viruses of herpes simplex and herpes zoster. In this case the lesions of the skin may be considered to be analogous to those found in the skin of patients suffering from herpes simplex and herpes zoster.

Penicillin in the Treatment of Common External Eye Infections in out-patients is described by MINTON⁸. The clinical results in blepharitis, conjunctivitis lachrymal sac infections and industrial eye injuries are excellent. Penicillin

⁷O'DONOVAN W. J. & MICHAELSON I. C. Epidemic Kerato-Conjunctivitis associated with Skin Lesions. *Brit. J. Ophthalmol.* 1946 Apr v 30 No 4 183-204 12 figs (including 3 in colour & 5 others on pls.)

⁸MINTON J. Penicillin in Treatment of Common External Eye Infections. *Brit Med J* 1946 Sept 7 324-8, 1 graph. [19 refs.]

is prescribed in the form of eye drops and ointment. He advocates the following method of preparation of penicillin eye drops. These contain 1,000 or 2,000 units per ml. in sterilized distilled water. Twenty ml. of distilled water are poured into bottles fitted with bakelite caps and rubber washers and then autoclaved at 10 lb (4.5 kgm.) pressure for half an hour. When penicillin drops are required two or four tablets of sodium penicillin (B & W) according to the strength required are added to each 20 ml. The tablets supplied are of three different strengths—0,500 10,000 and 10,500 units per tablet. The method of preparation of the ointment is as follows—it is prepared in the strength of 400 units per gramme. 200,000 units of penicillin in powder form are rubbed in a sterile mortar with a little sterile liquid paraffin. 500 gm. of eucerm L31 base (previously sterilized by heating in a sterotherm at 150°C.) are gradually incorporated. The ointment is transferred to sterile jars by means of a sterile spatula.

A biological assay of the penicillin eye-drops proved that the content of penicillin when the eye-drops were kept at room temperature, and the bottles frequently opened and exposed to air was 80 per cent. of its original potency at the end of fourteen days. The penicillin ointment was prepared without water and its stability probably lasts longer than six weeks. The drops and ointment have an ideal pH value for ophthalmic use and are therefore not irritating to the eyes. A number of adults, after using penicillin drops or ointment showed allergic skin reactions of the lids and the skin of the face. These cleared up in a few days when penicillin was stopped.

The use of Penicillin in Ophthalmology is also reviewed by PITTAR⁹. He points out that its application is strictly limited and its main use is only in superficial infections of the eye by local application, i.e. for conjunctivitis, corneal ulceration and blepharitis. It may also be found to have a great field in local prophylaxis, in preventing infection following corneal injuries in miners and industrial workers generally and it may practically abolish infection following intraocular operations. For local application he advocates drops with a concentration of 2,500 units per cc. frequency of application is essential. Clarification is needed regarding the use of penicillin in ointment form and in lamellae. Injections of penicillin into the anterior chamber and vitreous are probably only justified in desperate cases. For intraocular infection there seems to be a considerable field for the use of subconjunctival injection and there appears to be fairly good tolerance to daily injections of 500 units in 0.5 cc. of water. The various methods suggested such as corneal bath, ionization injections into the anterior chamber and vitreous all have special disadvantages.

[See also abstracts by DAKIUS and JOHNSTONE in this section below.]

Malaria—The ocular complications of malaria are reviewed by GRANT¹⁰. Opinions on the frequency of ocular complications in malaria have been divergent, depending considerably on variations in the definition of the term "complication" used by the different observers, as well as on the type of disease and thoroughness of examination. In some instances "complication" has been used to signify little more than coincidence whilst in others the term has been restricted to those ocular lesions which could be identified as local effects of the plasmodia.

On inspection of the figures available for the incidence of ocular complications from the standpoint of changes in the eyes which may occur as the result of the development of acute or masked malaria in otherwise healthy subjects, it

¹⁰GRANT, W. M. Ocular Complications of Malaria. *Arch Ophthalmology* 1948 Jan., v 23, No. 1 45-54. [57 refs.]

appears that the values of 10 per cent (POUCET 1878) and 20 per cent. (SALTZ 1890) which applied to a selection of chronically and seriously ill patients might be excessive whereas the opinion of ELLIOT (1920) that ocular manifestations were rare in India, was influenced by a reluctance to consider as a complication of malaria any ocular disease unless it could be demonstrated to be caused directly by the plasmodium.

DEDIMOS (1932) working in Macedonia, stated that the incidence of ocular complication was between 10 and 20 per cent. CARLOTTI (1918) in Greece gave the figure of nearly 10 per cent. FIALHO (1927) in Brazil reported an incidence of 15 to 20 per cent. TOULANT (1938) in Algiers concluded that ocular complications were relatively infrequent. Accounts of experience with ocular complications in World War II by TALBOT (1943) and ROBERTSON (1944) give the impression that ocular manifestations are relatively frequent although no actual figures are given.

Most observers agree that dendritic or herpetic keratitis is the most frequent ocular complication of malaria. Much less often interstitial keratitis has been noted. The keratitis usually occurs in one eye only and its onset is marked by discomfort, photophobia and lachrymation. The cornea is hyperaesthetic, and the lesion stains with fluorescein in the typical dendritic pattern characteristic of the herpes simplex virus in the corneal epithelium. Interstitial keratitis is associated with clouding of the stroma but without vascularization and severe forms have been described as keratitis profunda and disciform keratitis.

Haemorrhages in the ocular fundus have been noted by many observers. Small multiple retinal haemorrhages are usually located in the periphery of the retina and visual disturbances are therefore not observed. The haemorrhages are readily re-absorbed and rarely lead to retinitis proliferans. Large retinal haemorrhages are usually central and temporarily destroy central vision. They are much less common than the small haemorrhages and are limited to malaria with severe anaemia.

The ocular neurological lesions of most significance so far as they affect vision are those of the retina and optic nerve or of the pathways of the brain. The common manifestations are scotomas or loss of vision lasting from a few minutes to several hours followed by severe headache and persistently diminished visual acuity. Dizziness, orbital pain and tenderness with photophobia occur. Changes in the optic nerve and in the fundus sufficient to account for the amblyopia and amaurosis have been described in some cases while cerebral lesions have been considered responsible for the disturbances in others. Those lesions resulting in loss of vision which are evident ophthalmoscopically are optic neuritis or atrophy of the optic nerve and degenerative or haemorrhagic lesions of the retina and choroid. Opacities in the vitreous body and cyclitis are rarely reported except possibly for a mild iritis which occasionally accompanies herpetic keratitis. Cataract is also a rare complication. In the consideration of the usual disturbance in malaria the possibility of toxic effects of quinine in therapeutic use must be ruled out. The changes associated with toxic amblyopia or amaurosis due to quinine are sufficiently typical to be distinguished from malarial manifestations. Amblyopia and blindness due either to minute or massive doses of quinine are rare. At present the mode of toxic action of quinine on the retina is controversial and centres on the question whether the effects of the drug are a result of ischaemia due to alterations produced in the vessels or of a direct toxic action on the neural elements themselves but recent opinion seems to favour a direct action of quinine on the neural elements of the retina as a primary factor.

Relatively infrequently transient ocular motor disturbances, seldom with permanent paralysis have been ascribed to malaria. Of these paresis of the abducens nerve and facial paralysis with lagophthalmos have been reported.

Treatment of these ocular disturbances with anti-malarial drugs has in general been successful, except in the case of herpetic keratitis, caused by a virus for which specific chemotherapy is lacking.

The ocular manifestations in malaria are also discussed by BHATTACHARYA and GUHA¹¹. In the conjunctiva, marked pallor may be noted in malarial haemolytic anaemia, and icteroid discoloration in the bilious remittent type. In the cornea herpes simplex keratitis varying from mild forms to dendritic ulcers is found in protracted cases of the illness, more often in the convalescent or in the relapsing stages. In the vitreous and retina, haemorrhages have been noticed in a few cases. In rare cases thrombosis of the retinal veins, diffuse retinitis or retinitis proliferans as a sequel to retinal haemorrhages may be produced resulting in permanent impairment of vision. In the neurogenic lesions swelling of the optic disk from 1 to 2 dioptres has been noticed in a number of cases with meningitis and coma. In severe cases papilloedema, with exudates and haemorrhages was seen with dilated pupils and sluggish or absent light reaction. The malarial amblyopia seen was transitory in nature without any fundus changes.

Inequality of the pupils, convergent strabismus and nystagmus were also seen. The authors state that quinine amblyopia or amaurosis are not infrequent complications and that retinal and vitreous haemorrhages may occur after large doses of quinine in persons with a haemorrhagic diathesis and may accompany cutaneous, intestinal or urinary haemorrhages.

Scrub Typhus—The ocular changes amongst 451 patients suffering from scrub typhus are discussed by SCHIEF¹². The following external changes were seen: conjunctival hyperaemia occurred in 38 per cent of cases but disappeared during the second and third weeks of the disease; subconjunctival haemorrhages occurred in 68 per cent. The haemorrhages were massive, often covering one-third to one-half of the exposed sclera, and were usually bilateral. Echy-
mosis of the eyelids occurred in 1 per cent. of cases. An echar typical of the primary lesion of the disease resulting from a mite bite, was seen involving the upper lids in 0.5 per cent. of cases. A coarse irregular jerky incoordinate type of nystagmus, occurring only when fixation on an object was attempted was seen in 0.5 per cent. The following intra-ocular changes were observed. Venous engorgement was the most consistent change in the fundus and always preceded any of the other intraocular changes. It occurred in 67.2 per cent of the patients, with onset during the first or second week, frequently progressing until the veins were $2\frac{1}{2}$ times the diameter of the arteries. Accompanying the engorgement were irregularity in calibre of the veins and increased tortuosity of the vessels. Oedema of the optic disk and retina was seen in 36.1 per cent of cases. These were always both involved and the condition was always bilateral. In some cases, the swelling of the disk was marked and resembled papilloedema. Retinal haemorrhages, usually superficial were found in 6.6 per cent of the patients. Fluffy white exudates occurred in 4.9 per cent. These were usually of the cotton wool variety though some resembled gangliform degeneration. The haemorrhages and exudates usually occurred in patients who also had oedema of the retina and disk. Dust like vitreous opacities most numerous in the posterior vitreous without further evidence of uveitis, were seen in 4.6 per cent and definite uveitis in 1.3 per cent. of the patients. The uveitis was usually indolent in character with slight photophobia and usually without ciliary injection. It was nearly always associated with oedema of the

¹¹BHATTACHARYA, B. P. & GUHA, G. S. Ocular Manifestations in Malaria. *Indian Med. Gaz.* 1946, Feb. v 81 No. 2, 79-80.

¹²SCHIEF, H. G. Ocular Changes in Scrub Typhus. A Study of 451 Patients. *Bull. U.S. Army Med. Dept.* 1946, Apr., v 5 No. 4, 423-7 4 figs.

disk and retina. Visual acuity was undisturbed except in patients with uveitis who occasionally complained of blurred vision. From the pathological investigations available it would appear that the primary lesion in the eye consists of an inflammation of the highly vascular uveal tract. This might be expected for one of the characteristic pathological changes of scrub typhus is a vasculitis and perivasculitis of the smaller blood vessels. The incidence of vitreous opacities and bilateral uveitis supports such pathological findings. Even though the clinical picture suggests a retinopathy, the disturbance in the choroid is probably the underlying factor.

Visual Defects in Prisoners-of-War from the Far East are described by HOBBS & FORBES.¹² More than 2,500 men liberated from Japanese prisoner of war camps were seen. Defects of vision recovered or still present were a prominent feature of the history: they were classified into three broad groups—

Group I—defective reading vision only, usually transient.

Group II—transient blurring of both reading and distance vision.

Group III—a persistent defect of both reading and distance vision.

Patients in groups I and II mainly presented problems of refraction and appeared to have had a temporary asthenopia associated with their very debilitated condition before liberation. The visual acuity was within normal limits, and no abnormalities of media fundi or ocular movements were seen. Group III numbered about 250 persons and comprised a few men with active ocular disease, a number with fully correctible refractive errors in whose visual fields no scotomata appeared, and a larger group in whom correction with lenses produced little or no improvement and whose visual fields showed absolute or relative scotomata to white test objects. These cases form a group of 163 cases of partial optic atrophy. The history of 89 per cent of these 163 cases was of gradual deterioration of vision after the first or second year of captivity, occurring as a general blurring of vision or as scotomata. The visual loss increases over a period of weeks or months, but a rapid onset was not uncommon and in 11 per cent the visual loss had developed within twenty-four hours. In many cases the onset was insidious and unrelated to other disease. In regard to refraction 6 per cent had visual acuity of less than 6/60, 55 per cent had visual acuity between 6/60 and 6/24, 33 per cent, though subnormal, were better than this, and 6 per cent had 6/6 in both eyes.

Pallor of the central halves of the disks was present in most cases. Signs of retinal disturbances were not common and when present were noted between the macula and the disk. Perimetry showed no significant constriction of the peripheral fields in any except the more severely affected cases. Examination of the central fields revealed various types of defects, all of which lay in the centro-caecal area: the most common finding was bilateral absolute central scotomata to 2, 5, 10 or 15/2,000 white, and in such cases the associated loss of visual acuity was correspondingly great. In others less severely affected, scotomata less dense and less centrally placed appeared, and these often took the form of central and paracentral relative scotomata, with eccentric absolute nuclei, which in some cases formed a partial ring and left the fixation area clear. In others there were minute scotomata about the central area, where the 2 mm. white object appeared to flash on and off.

Group III cases, showing scotomata and partial optic atrophy, were closely related to preceding infection, particularly malaria and dysentery. In the former an increased metabolism and in the latter decreased absorption from the diseased intestine producing a greater lack of those factors which normally prevent the development of this syndrome.

¹²HOBBS, H. E. & FORBES, F. A. *Visual Defects in Prisoners-of-War from the Far East.* *Lancet* 1946 Aug 3 149-53, 5 figs. [15 refs.]

The response to treatment was poor. The superiority of animal protein over yeast in prevention and treatment suggests that some factor besides Vitamin B contained in animal protein, is necessary to prevent the onset of these lesions, and that the lack of protein is a precipitating factor in the disease. It may well be that the rôle of protein consists in promoting the biosynthesis of vitamins in the intestine.

Nutritional Retrobulbar Neuritis or nutritional optic neuropathy, is reviewed by MOORE¹⁴. The aetiology is still far from complete. He is of opinion that it can be excluded from beriberi though it can be associated with it. The response of the visual condition to autoclaved yeast and the investigations with thiamin in the prisoner-of-war camps, are impressive evidence against beriberi. In West Africa nearly all cases were either accompanied or preceded by hyporiboflavinosis, but it would not be safe to state that riboflavin deficiency caused the neural condition for trials with riboflavin have never been sufficiently extended. Lack of riboflavin is no doubt an important causal factor but other vitamins of the B complex excluding thiamin may also share in the cause. The same is partly true for nicotinic acid, though there is more evidence that lack of this vitamin is not directly concerned. Experiences in prisoner-of-war camps appear also to support this view. Treatment has yielded important results provided it is begun early, the dosage (marmite or brewer's yeast) is high and it is maintained over a long period.

The clinical features are important for there are distinct variations and superimposed conditions to be found. Keratitis was rare in Nigeria, but common in Sierra Leone and apparently in prisoner-of-war camps. The Jamaican cases were fulminating. Beriberi is rare in Nigeria, but common among ships crews, on a diet of rice and salt fish from Sierra Leone and Liberia. In Nigeria, retrobulbar neuritis was extremely common but in certain areas only or under bad conditions which existed in some schools before the war. It was not seen in those areas where yams or sweet potatoes or better class cereals, formed the staple carbohydrate. As early as 1933 the author was convinced that manioc was the dietetic cause for the disease was essentially confined to the manioc eaters. But in Jamaica manioc was replaced by sugar cane in Sierra Leone and Spain (civil war conditions) largely by rice and in China and the Far East solely by rice. Where the rice was unpolished or as in prisoner-of-war camps reinforced with barley and soya bean there was least evidence of retrobulbar neuritis. A theory based on an exogenous toxin therefore can only be upheld if it can be proved to be common to all conditions. There is an obvious alternative explanation—a theory based on an endogenous breakdown. It may be that certain foodstuffs do possess inhibitory toxic factors and also help to accelerate metabolic breakdown (e.g. cyanogenetic factors—alcohol in secondary pellagra).

What has been established is that under conditions of duress or environmental restrictions, leading to an insufficiency in normal intake of protein (and, to satisfy hunger a relative over-consumption of energy foodstuffs poor not merely in vitamin B₁ but in all the B vitamins) nutritional retrobulbar neuritis has been common. Other syndromes such as beriberi may of course co-exist. Why say that rice can cause only beriberi, when it is poor in all nutrients? Where there is a gross dietary imbalance and where cereals of poor quality are almost the sole source of energy and protein is deficient then we can be certain that this visual complaint and the associated primary deficiency status must remain. It is not enough to ensure an adequate crop of rice or manioc—we must also aim at a vast improvement in the variety of carbohydrate foods and in the diet as a whole and a rise in the economic standards of life.

¹⁴MOORE, D. F. Nutritional Retrobulbar Neuritis. Nutritional Optic Neuropathy. *Lancet*. 1946, Aug. 17. 48-8, 3 figs. [33 refs.]

Nutritional Optic Neuropathy.—The syndrome of epithelial and nervous lesions complicated by nutritional optic neuropathy is reviewed by WRIGHT¹⁵ He found defective vision to be a cause of constant complaint and attributed its origin to deficiency of vitamins A and B he therefore introduced in 1927 the active treatment with yeast and cod liver oil. In Sierra Leone the dietary is deficient in protein and hence in sulphur. In 1936 he described the experimental treatment of the syndrome with organic sulphur using Contra mine parenterally in some cases and ichthyol orally in others. Judicious sulphur therapy was of great benefit to the patient and resulted in economy in treatment. Although good clinical results have consistently been obtained by combined sulphur and vitamin therapy in Sierra Leone he has seen no record of its use in nutritional optic neuropathy.

The Nature of Starvation Amblyopia in 277 cases in Camp Nakom Paton is analysed by HAZELTON¹⁶ The aetiology of the disease seems to be bound up with a combination of vitamin deficiencies. The disease resolves itself into two parts: (1) Easy exhaustion of the ciliary muscles which is cured by the administration of sufficient doses of thiamin at least 1 000 international units intramuscularly each day for 14 days. Also the symptoms of eye strain (pain in the eyeballs frontal headaches, excess lachrymation heaviness of the lids and tired feeling of the eyes which increased after reading) were alleviated by the administration of thiamin. (2) A condition of degeneration of the cones of the retina which itself is probably brought about by the lack of sufficient photo-sensitive substance for these receptors. The former is shown (a) by lowering of the visual acuity (b) inability to differentiate objects close together (c) interference with colour vision. The latter is postulated from the fact that the colour of print appears to change on reading from black to green or yellow. Two facts emerge from this—

1. There is a definite relation between eyestrain and vitamin B₁ deficiency.
2. Sufferers from avitophthalmia are liable to sustain further damage to their cones in bright light they should not work in sunlight and should wear dark glasses. Any degeneration of the retina is probably permanent and in early cases every effort should be made to supply a well-balanced diet failing the elucidation of the specific factor causing the disease. The results of treating cases of nutritional amblyopia of short duration with 10 eggs per day for thirty days were very gratifying. All cases undergoing this treatment showed a distinct improvement.

The Ocular Symptoms and Signs associated with Deficiency of Vitamin B Complex are discussed by FERNANDO AYUYAO and CRUZ.¹⁷ Their report is based on the observations of 590 adult patients in the Philippines and is the first epidemic of this nature ever reported in that country. The chief complaint was dimness of vision in both eyes the cause of which was (1) chronic retrobulbar neuritis (2) superficial vascularizing keratitis or (3) both affections co-existing. The patient invariably gave the history of having subsisted for some time on a diet very deficient both in quantity and in quality. They were healthy up to the time of onset of their complaint. Adult males and females were attacked. In females pregnancy and lactation were predisposing factors. In many patients associated signs and symptoms of vitamin B complex deficiency were observed namely angular stomatitis glossitis numbness around the mouth hyperaesthesia or hypoaesthesia in the extremities and other manifestations.

CORRESPONDENCE.

In the abstract of the paper by BERNASCONI on trachoma [this *Bulletin* 1945 v 42, 488] the statement is made that the author treated a small number of incipient cases of trachoma with a preparation containing vitamins A and D by the mouth, without local applications. The author points out that 24 cases were treated, of which 9 were incipient and 15 in the granulomatous stage (2 having complications). The results were good. He also remarks that cod liver oil has been used with good effect as the source of vitamins A and D—Ed

TROPICAL ULCER.

L. NATH T. Tropical Ulcer in the Hissar District of the Punjab. *Indian Med Gaz.* 1946 Apr-May v 81 Nos 4/5 169

11. LUTHRA, P. N. Ulcus Tropicum in Fazilka (Punjab) *Ibid* 169-71

1. It is pointed out by the author that whilst tropical ulcer has been reported in the humid climate of Assam and South India, and other parts of the country no cases had been reported so far from the Punjab

The paper discusses 60 cases seen in the Hissar district of the Southern Punjab where rainfall is very low and the soil is mostly sandy

The clinical, aetiological and microscopic features described by the author follow the now well recognized picture. Two points of interest are that most cases occurred under the age of 18 years, and that they were most frequent between September and January

Three groups of 20 patients were subjected to different treatments, namely—(1) scraping, followed by dressings of 5 per cent. copper sulphate (2) scraping and sulphonamide powder and (3) strapping with leukoplast for at least 10 days

The first two groups took about 35 days to heal, whilst the third did remarkably well and healed in 15 days.

The author noted scars on the lower limb in several patients examined for medico-legal identification and presumed therefrom that the ulcer had existed in the district for a number of years.

ii. This author saw 106 cases of tropical ulcer in the out patient department in Fazilka a small town in the Ferozepore district of the Punjab with a population of 26 000. The climate is very hot and dry in summer and cold and dry in winter. The average rainfall is about 10 inches but in 1944 it reached about 16 inches.

The author describes the disease as assuming a mild epidemic form after the unusually heavy rains in 1944 and a milder epidemic was also noticed after the summer rains in 1945. [The use of the word epidemic is perhaps something of an overstatement.]

The description of the cases closely resembles that given by the author quoted in the preceding abstract. Over 50 per cent. of the patients were under 16 years of age and 95 per cent were under 30. Only 10 were females.

Twenty-eight hospital patients were treated by complete rest and daily cleansing of the ulcers with a solution containing 3 drachms of copper sulphate 1 drachm of carbolic acid and 1 ounce of water. The ulcers were then dressed with boro-iodoform. With this treatment the average stay in hospital was 14 days. When half of the patients were treated with dressings of magnesium sulphate and sulphonamide powder in equal parts the average stay in hospital was 20 days. Penicillin dressings used in one case only did not accelerate recovery.

The author's experience that the disease is one affecting the poor and ill nourished agrees with that of the previous author writing from Hissar and indeed with that of most observers and he sounds a note of warning that it may well spread and assume severe epidemic proportions under the serious food conditions now prevailing in India, a danger which health authorities and others should take anticipatory steps to meet.

[Although these papers have little new to add to the large dossier of tropical ulcer, the close resemblance between these independent testimonies in different parts of a Province where tropical ulcer was not believed to occur is significant and there is sound sense and humanity in the timely reminder for the need to take advance account of this additional potential complication of the already severely taxed vitality of the people in the famine-afflicted regions of India.]

H J O'D Burke-Gaffney

GOLDEN A & PADILLA, E. Tropical Ulcer in Guatemala. Pathologie, Bacteriologie, Mycologie and Clinical Aspects. *Arch Pathology* 1946 June v 41 No 6 612-30 3 figs.

This paper represents the results of observations made by the authors on 24 patients suffering from tropical ulcer. All the patients originated in the lowlands—from sea level to 1 000 feet—and were predominantly American Indian and Indian-Caucasian though all types in the lowlands were included Indian, Caucasian and Negro.

The patients comprised members of age-groups from 11 to 56 years of both sexes. Sex and occupation did not appear to affect incidence significantly.

Full histories were obtained and physical and laboratory examinations were made and the investigation included the dietary history of the patients. No common nutritional deficiency was noted.

Routine clinical laboratory tests revealed nothing of new importance and bacteriological examination including attempts to isolate fungi were inconsequent and added nothing to the list of recognized flora.

The authors exclude various causative factors in their series one by one, but place most significance on the biopsy findings. After describing the general

and usually recognized histological features of tropical ulcers they note that the distinguishing feature in all cases was to be found in the vascular changes. These consisted essentially of thickening and narrowing of the lumina of vessels which were occasionally obliterated and sometimes recanalized. These signs were found, to some extent, alike in arteries, veins and capillaries.

Detailed descriptions of these histological changes are given and the authors believe that they are primary vascular changes and not secondary to inflammation. Arguments are given in support of this thesis the chief of which are that (1) even the most severe vascular lesions were found in all cases at an early stage (2) the most pronounced vascular changes were situated away from the zones of greatest inflammatory exudate (3) the condition is entirely different from the endarteritis or vasculitis commonly encountered as secondary to inflammation.

In the absence of any other specific factors, the authors consider that the vascular feature stands out clearly for it was common to all cases. They discuss the possible causes of these vascular changes but were unable to find any one specific reason for the interference with local blood supply. They consider that treatment of tropical ulcer should aim especially at restoring the adequacy of the blood supply to the part.

[Among the vast number of factors which have been indicted as causes of tropical ulcer there have frequently been included that of inadequate blood supply to the affected part. Where the authors' further confirmatory study is especially valuable is in the carefully described and well-illustrated histopathological investigations.]

MISCELLANEOUS DISEASES

- I. MANSON BARR, P. E. C. & CHARTERS, A. D. Epidemic Thrombophlebitis in the East Africa Command. *Lancet* 1946 Sept. 7 833-5 3 figs.
- II. FISHER, A. C. & LENDRUM, A. C. Epidemic Thrombophlebitis [Correspondence.] *Ibid* Sept. 21 438.

I. The authors describe a syndrome of recurrent thrombophlebitis accompanied by pyrexia often relapsing and sometimes associated with stiff neck, among East African soldiers. No previous record of this condition was known to the authors but they quote GELFAND who in his book "The Sick African" refers to the condition of acute thrombophlebitis of unknown aetiology described in N Rhodesia by FISHER [this *Bulletin* 1942, v 39 199].

Occasional cases had been seen in the East African Command during 1941-1943 but in 1944 the disease began to assume epidemic proportions and cases were observed independently at three different centres most, but not all, of the 627 patients with this syndrome, admitted to two General Hospitals had previously been treated for venereal disease at special centres.

The authors describe the clinical features observed in 145 cases three varieties of the syndrome were seen —(1) a short term fever with stiff neck often followed by relapses (2) thrombophlebitis affecting one or more limbs, tending to relapse (3) pyrexia, usually relapsing without evident phlebitis. As stated above most of these patients had received treatment for venereal disease, which involved venepuncture but 23 did not give a history of infection. The interval between the last injection and the onset of symptoms varied from three days to seven months. The first variety short-term fever with stiff neck, developed either as the first phase of the syndrome or as a sequel to previous attacks of phlebitis it lasted 2-30 days, usually about 4 it usually relapsed,

with stiff neck or thrombophlebitis but occasionally without either. There was no sign of cervical thrombophlebitis. Laboratory examinations including some attempts at bacteriological culture were negative, except for relative lymphocytosis in a few cases. The second variety, thrombophlebitis affecting one or more limbs, was either acute or subacute in most cases, but a chronic form, a form with involvement of the portal vein, and a form associated with arteritis are described. Again laboratory investigations were negative and biopsy of the affected vein in 6 cases showed simple thrombosis only, with no evidence of inflammation of the wall of the vein. The veins of the legs were most commonly affected, but in 20 of 105 cases the veins of the arm were thrombosed. In no case was embolism noted.

In the third variety, the pyrexia was irregular and lasted for 3-21 days without evident phlebitis; in many of these cases the diagnosis was suggested by a history of recent anti-syphilitic therapy.

The authors discuss the differential diagnosis of these conditions.

The cause of this disease is still unknown. That it may be due to a virus, possibly transmitted during intravenous medication for syphilis, is suggested by the relative lymphocytosis, the negative bacteriological findings and the fact that the curve of incidence followed quite closely the curve of incidence of hepatitis which was related to administration of arsphenamine. No antibodies to Rift Valley fever were found in two patients examined. It is possible that the administration of arsenic or bismuth predisposed to the present syndrome, perhaps by rendering the veins susceptible to infection. There was no evidence that this thrombophlebitis was related to marasmus—most of the patients were well nourished. The authors note that thrombophlebitis is not common in the civilian Africans of the area.

II. In this letter Fisher and Lendrum refer to the pathological findings in the veins in the Northern Rhodesia cases mentioned above.

It has come to be appreciated (A.C.F.) that only a short stretch of the vein was primarily involved and microscopy of this zone has now revealed a peculiar form of inflammation characterised by extreme proliferation of young capillaries in the disrupted media of the vein and by the presence of phloxaophil intracytoplasmic inclusions.

JACOBY H. Curative Treatment of Lathyrism, a Disease of the Nervous System. *Indian Med Gaz* 1948 v 81 Nos. 6/7 246-7

The author reports favourably on prostigmine.

Cox C D & ARBOGAST J L. Molluscoidosis. *Amer J Clin Path* 1945 Dec v 15 No 12 567-70 [14 refs]

This paper reports a case of molluscoidosis in a 27 year-old American infantry man who died on the 8th day of disease. He had been 21 months overseas 20 of which had been spent in Burma; the month preceding admission to hospital he had been located at Dujayn in Assam. Illness started acutely. There was a swinging temperature up to 105°F. Liver and spleen were both palpable and scattered pustules appeared over the entire body. Clinical diagnosis was one of generalized septicæmia of undetermined ætiology. Post mortem abscesses averaging 0.8 cm. in diameter were present in the skin, liver, spleen, lungs, lymph nodes, epididymis and testicle. They were most numerous in the lungs where they were becoming confluent. Histologically they were characterized by a central zone of coagulation necrosis surrounded by a hæmorrhagic zone, numerous polymorphonuclear leucocytes were

present. A motile Gram-negative bacillus, isolated from the blood and skin lesions during life and from the lesions post-mortem, was identified as *Malleomyces pseudomallei* (Pf) Whitmore.)

S. P. Bodson

ASHLEY, P. External Otitis in the Tropics. *U.S. Nav. Med. Bull.* 1946 Aug v 46 No 8 1230-36 4 figs.

Ashley states that the cases of external otitis which occur in ships operating in tropical waters may be divided into three categories.

In the first group the men complain of pain in the ear discharge, partial deafness itching or burning. The auditory canal is partly or wholly blocked with a cheesy or flaky mass consisting of cellular debris and moist exudate, in which purulent matter may occasionally be incorporated. If the meatus is cleaned its walls are found to be raw red and, sometimes, bleeding they may also be slightly oedematous.

Ashley recommends that the ear should be thoroughly cleansed and if X-ray therapy is not available (he regards X rays as the ideal treatment for all forms of external otitis) the meatus should then be swabbed with a 4 per cent. solution of boric acid in 50 per cent. ethyl alcohol. Thereafter a cotton wick impregnated with 10 per cent. aqueous solution of sodium sulphadiazine should be inserted and left in place. This dressing should be changed thrice daily. On the third day if the walls are dry the treatment is changed the toilet of the ear is carried out twice daily and a search is made to determine which of ten preparations—the formulae for which are given—will suit the patient best and complete the cure. The preparations vary from sulphanilamide powder to a lotion containing 1 gramme of benzoic acid, and 1 gramme of salicylic acid in 30 cc. ethyl alcohol. The ten preparations are shown below —

Formula No. 1	Gm. or cc.
Salicylic acid	1.0
Ammoniated mercury	1.0
Rose water ointment	30.0
Mix.	
Formula No. 2	
Ammoniated mercury	1.0
Petrolatum	30.0
Mix.	
Formula No. 3	
Salicylic acid	1.0
Ethyl alcohol 95-per cent. to make solution	30.0
Formula No. 4	
Sulphanilamide powder	
This is best instilled with a powder blower	
Formula No. 5	
Sodium sulphadiazine ointment 5-per cent.	
This is a new item in the Supply Catalogue.	
Formula No. 6	
Sulfathiazole powder	1.5
Petrolatum q.s. ft.	30.0
Mix.	
Formula No. 7	
Salicylic acid	3.0
Ethyl alcohol 95-per cent. to make solution	30.0
Formula No. 8	
Thymol	0.6
Cresatin q.s. ft.	30.0
Mix.	

Formula No. 9

Ichthammol	1 2
Naphthalan	6-0
Zinc oxide	15-0
Starch	15-0
Petrolatum q.s ft	60-0
Mix.	

(This preparation is not available at sea but is very effective in Group 3 cases.)

Formula No. 10

Benzoic acid	1-0
Salicylic acid	1-0
Ethyl alcohol 95-per cent. to make solution	30-0

Benzoic acid was not available but we feel that this so-called liquid Whit fields would be of use in some cases.

The second variety of otitis externa is more acute. The patient's temperature may be raised to 103°F and the ear is exquisitely tender. The walls of the auditory canal may be oozing or dry, but they are very oedematous. This variety of otitis externa responds to rest in bed, oral administrations of sulphadiazine and the application of heat to the ear from a partly filled hot water bottle. After 24 hours the patient is usually so far recovered that he will submit to local therapy. The meatus is then cleansed, and a wick impregnated with metacresyl acetate (cresatin) is inserted and renewed thrice daily. After some 3 or 4 days he may leave his bed, and local therapy continues as for cases of Group I.

The third group consists of patients who complain of itching and occasional slight pain in the ear. The walls of the canal are found to be dry and scaling. The condition may arise *de novo* or may be a sequel to the other types of inflammation described above. Treatment consists in carrying out the toilet of the ear regularly and using one or other of the ten applications which the author has listed for use in cases of Group I.

Ashley believes that the adverse climatic conditions of the tropics associated with the entry of water into the ear whilst the patient is bathing under a shower or swimming and the removal of wax from the ear with toothpicks and other implements, should all be considered as aetiological factors. In cases of Group 3 the production of dry wax or no wax or oil at all in the ear canal leads to scaling and fissuring of the skin giving the picture commonly known as eczema of the external ear canal. Fully developed this eczema is identical with the picture seen in Group 3 and may quickly develop into either of the other two types.

R M B Mackenna.

KEAN B H & TUCKER, H A. *Etiologic Concepts and Pathologic Aspects of Ainhum. Arch Pathology* 1946 June v 41 No 6 639-44 1 fig [33 refs.] [Refs. in footnotes.]

The authors group the aetiological factors comprising the many theories as to the causation of ainhum under three general headings: infectious, constitutional and mechanical.

In this paper they discuss the literature under these general heads and then describe the records of 45 sufferers from ainhum on the Isthmus of Panama 12 of whom they had observed clinically.

All the patients were negro males and the little toe was the only digit involved. A deep encircling groove separated the toe from the remainder of the tarsus at the level of the digito-plantar fold. In advanced cases the constriction progressed until only a thin pedicle kept the small potato-like toe to the foot.

The histopathological features conformed to the recognized descriptions of ainhum but the authors consider that in published reports undue significance is commonly placed on a number of features and they express the following opinions —

- (1) The groove is not caused by a *constricting band* of fibrous tissue.
 - (2) Identical epithelial changes may be seen in the toes of those not suffering from ainhum.
 - (3) The vascular changes noted are not specific to ainhum.
 - (4) The nerve and gland changes do not appear significant. The authors found it difficult to evaluate the atrophy of bone and the subcutaneous inflammatory reactions, which seemed to be significant but the evidence that the essential lesion of ainhum might be chronic osteomyelitis was not impressive, although the low-grade cellulitis and fibrosis of the corium were more suggestive.
- The authors conclude that the cause and pathogenesis of ainhum are not clear but that the racial factor seems most important.

GENERAL PROTOZOOLOGY

PLAUT, A. The Problem of Human Toxoplasma Carriers. *Amer J Path* 1946 Mar v 22, No 2 427-31 6 figs. on 1 pl.

In the case of a boy who died of severe jaundice, associated with enlargement of the liver and spleen and ascites and also in the case of a woman who died of peritonitis following operation for intussusception, bodies presumably parasitic in nature were found in the myocardium. In the first case two masses were seen in enlarged muscle-fibres. Each mass, which had a fairly distinct outline consisted of numerous closely-packed particles about $1\frac{1}{2}$ in diameter. In the second case a single group of somewhat larger radially arranged bodies, each with a central nucleus was seen. In neither case was there evidence of parasitic invasion elsewhere in the body. Slides and photographs were submitted to a number of experts, who failed to agree as to the significance of the structures, suggesting among other things that they were sarcosporidia, toxoplasma or contaminantia. The author calls attention to the organisms which are illustrated in photographs because of their importance from the point of view of the discovery of carriers of toxoplasma infection.

GENERAL ENTOMOLOGY

BEADLE, L. C. An Ecological Survey of some Inland Saline Waters of Algeria. *J Linnean Soc Zoology* 1943 v 41 No. 278 218-42, 1 fig [38 refs.]

This paper is the result of an expedition to study the saline inland waters in Algeria in the winter of 1938. They ranged in density from 1 000 to 1 172

(fresh water=1 000 sea water 1 022) Analyses for the various ions were made pH values alkalinity and other data are given. The fauna and flora found can be divided into three groups —(i) freshwater species only found in low salinities (ii) forms only found in intermediate salinities (iii) forms capable of living in extremely saline waters. Many interesting and useful results of ecological importance are given but few forms of direct medical importance were found. *Aedes detritus* and *Aedes caspius* which are confined to saline waters were recovered several times. *Anopheles multicolor* was found once in stagnant water having a density of 1 008

WANSON M & LEBIEU B. Un nouvel Anophèle cavernicole du Congo belge *Anopheles (Myzomyia) rankhooi* spec. nov. [A New Cavernicolous *Anopheles* from the Belgian Congo] Reprinted from *Rev. Zool. Bot.* 1945 Dec 29 v. 39 No. 1 118-29 19 figs.

In the lower part of the Belgian Congo near Thysville there is a very large cave which is known to extend at least a mile from its entrance. It contains a remarkable fauna, including a blind fish, cave crickets and so forth, also two giant species of *Phlebotomus*.

The authors here describe a new species of *Anopheles* from this cave. The early stages have been found in total darkness in a chamber some three hundred yards from the entrance. They occur in small basins in the rock which are filled with water that drips from the roof; the adults are found in the same place and it is thought that they never leave the cave but feed on certain bats (*Myiopsyllus*) which are abundant.

The adult mosquito is large and dark without ornamentation on the legs or palps and with only some very obscure pale spots on the wings; there are small differences in the wing markings between the male and female. The morphological characters of the larva and adult indicate clearly that it is a *Myzomyia* and that it probably belongs to the group *Eomyzomyia* with affinities to *A. wilsoni*. [So far as we are aware this is the first record of a completely cavernicolous mosquito.]

KNIFE F W. Improvements in Equipment for killing both Larvae and Adult Mosquitoes with DDT. Reprinted from *Agric. Engineering* St Joseph Michigan. 1945 Nov., v. 26 No. 11 459-62 464-468, 5 figs.

The introduction of DDT involves changes in spraying equipment because the dosages applied and the degree of atomization required differ from those of preparations formerly used.

A hand gun of the Cobra type has been developed which will operate at pressures between $\frac{1}{2}$ and 1 atmosphere (7-14 lb./sq in.) The orifice is 1 mm. in diameter and with a working pressure of 0.5 kgm./cm² ($\frac{1}{2}$ atmosphere) this will deliver 2.5 cc. of DDT-oil solution per minute. This permits easy coverage of an acre with one quart of oil. The same type of nozzle can be used without the hand plunger pump by attachment to an independent air supply. The nozzle can be adjusted so that, at 1 atmosphere pressure it will deliver from 2.5 to 110 cc. per minute. Up to 54 cc. an excellent pyrethrum type spray is produced (atomized mist) and just above this a wet spray is formed which is suitable for treating walls.

A small hand operated air-pump has been devised for use with the sprayers. This is operated by a lever in the same way as the ordinary knapsack oil-spray pump. It develops a pressure up to 2 $\frac{1}{2}$ atmospheres. It can either be used in conjunction with a knapsack tank or the air can be delivered to a hand sprayer with a container. Two such pumps strapped on a brace on the back of an operator will supply air for a single spray-gun carried by another operator. This arrangement is convenient for indoor spraying where the sprayer has to be manoeuvred over furniture etc.

Types of spray patterns are discussed. The fan-shaped spray is considered preferable to the round spray for careful treatments in furnished houses. Fan-shaped sprays can be produced by suitable nozzles, both with air-atomized and pressure-atomized (whirling jet) sprays.

A convenient extension arm can be made from 6 mm. aluminium or copper tubing led through bamboo poles drilled lengthwise. An extension of this type four to five metres long is not too heavy and is useful for spraying high barns, etc.

J. R. BURTON

DAVID W. A. L. The Quantity and Distribution of Spray collected by Insects flying through Insecticidal Mists. *Ann Applied Biol* 1946 May v 33 No. 2 133-41 2 figs & 1 pl. [12 refs.]

If a housefly or a mosquito (*Anopheles gambiae*) flies through a mist of finely divided insecticide droplets accumulated in transit can be seen by subsequently examining the wings. On other parts of the body oil-carried insecticides spread rapidly but by use of an aqueous spray droplets can also be found on the antennae, eyes, mouthparts, large body bristles, the halteres and on fine hairs guarding the anterior spiracles. If a spray mist is produced with oil dyed with Sudan III, and the flies are dissected at intervals after exposure, it is found that the dye penetrates the integument, is extracted from the haemocoel by the Malpighian tubules and excreted through the anus. Houseflies with mouth and anus blocked were found to show large quantities of dye in Malpighian tubules and rectum one hour after spraying.

A colorimetric method is described by which the quantity of spray drops packed up during flight can be estimated. With both *Musca* and *Anopheles* about three times as much spray is deposited on the wings as on the body. With insecticides which do not cause paralysis, much of this deposit is removed during the course of twenty-four hours. Deposit on the wings is removed by cleaning movements of the legs and there is also a general absorption and excretion. Penetration of the cuticle does not appear to occur in dead insects.

The quantity of spray accumulated depends on the physical qualities of the mist, especially on the size and number of drops. Much more is accumulated directly after spraying than in an equivalent period with a mist four to ten minutes old. The addition of a small quantity (5 per cent.) of a non-volatile oil reduces evaporation of the droplets, which therefore remain of large size as a consequence, many more impact on flying insects.

By the quantitative method it is possible to estimate the median lethal dose of different insecticides as deposited from spray mists. Thus —

Insecticide	Median lethal dose (mgm. per kgm live weight)			
	<i>Musca</i> (3-5 days old)		<i>Aedes</i> (1-4 days old)	
	Males	Females	Males	Females
DDT (0.3 per cent. sol.)	6.0	9.0	5.5	8.0
Gammexane (0.3 per cent. sol.)	2.0	3.0	3.0	3.5
Pyrethrins (0.1 per cent. sol.)	—	—	0.5	1.0
Pyrethrins (2.0 per cent. sol.)	31.0	33.0	—	—

POTTER C. & GILLHAM E. M. Effects of Atmospheric Environment before and after Treatment, on the Toxicity to Insects of Contact Poisons. I. *Ann Applied Biol* 1946 May, 33 No 2 142-59 7 figs. [16 refs]

The authors discuss the influence of temperature and humidity on precise laboratory testing of insecticides. Experiments are recorded in which the effects of keeping an insect cool or warm before and after spraying are related to the mortality caused by different contact insecticides in various media. The insect used throughout was the flour beetle *Tribolium castaneum* which was reared at 80°F (27°C).

It was found that exposure of the insects to cool conditions (50-60°F) or warm conditions (80°F) for one to twenty four hours before spraying did not have a great effect on the results. However insects kept under warm conditions after spraying were much more resistant to most of the insecticides tested than those kept under cool conditions. The actual ratios of potency of the different insecticides were as follows —

Poison	Medium	Ratio (potency of insecticide with cold storage after treatment as proportion of that under hot)
Pyrethrins	Aqueous	2.67 and 5.01 (2 expts.)
Pyrethrins plus Terpeneol		7.21 and 6.90
Lauryl thiocyanate	Ethylene glycol Oil	1.43
Nicotine		1.23
Dinitro-o-cresol		1.46
DDT		2.61
Wakefield white oil ..		0.87

It will be observed that the only spray which caused greater mortality under warm conditions was the chemically inert Wakefield white oil.

It is believed that this effect of temperature must be referable to the physiological condition of the insect rather than to any direct physical action on the insecticide.

LARSEN Ellmør B & THOMSEN M. The Influence of Temperature on the Development of some Species of Diptera. Reprinted from *Vidensk. Medd. fra Dansk naturh. Foren.* 1940 v 104 75 pp 18 figs. [39 refs.]

It is difficult to obtain accurate figures for the rate of development of flies which breed in dung and the optimum conditions cannot be precisely defined. Even when experiments are carried out in a thermostat fermentation may raise the temperature of the medium or evaporation may lower it and so invalidate the results. This paper is an account of very extensive experiments in which every attempt was made to eliminate these sources of error. Five species of diptera whose larvae live in dung were used: *Musca domestica*, *Stomoxys calcitrans*, *Lyperosia irritans*, *Hematobia stimulans*, *Scatophaga stercoraria*.

With *Musca domestica* the minimum duration of the pre-imaginal period was 6.9 days at 33°C. Above this temperature there was some retardation and 40°C was too hot causing 100 per cent mortality. Development was slowed down by temperatures below 33°C to 15-66 days at 21°C and 54 days at 14.2°C. The developmental zero was in the region of 12°C, though some development occurred at as low a temperature as 9.2°C. The various stages of development—egg, feeding larva, pre-pupa, pupa—were affected in a roughly proportionate manner.

Stomoxys calcitrans developed most rapidly at 31.4°C. with a pre-imaginal period of 10.75 days. The rate for the whole zone of temperature from 29°C. to 33°C. closely approximated to this figure. Above 33°C. there was a marked retardation, and 35°C. proved fatal. At 15.7°C. development took 44 days. The developmental zero was about 12°C. There was no indication of a diapause occurring in either of the above species.

Lyperosia irritans was more difficult to rear in the laboratory. The shortest duration of the pre-imaginal period was 7.54 days at 32.3°C. A sudden drop in temperature below 18°C. seemed often to induce a pupal diapause. *Hematobia stimulans* is also difficult to rear in the laboratory. This species was adversely affected by much lower temperature than the others: a fact probably correlated with its scarcity during the summer and its commonness in spring and autumn. The maximum rate of development (pre-imaginal period 11.1 days) occurred at 28.3°C. The threshold of development was at about 9°C. A diapause may possibly occur during development.

Scatophaga stercoraria was found to be even more easily harmed by high temperatures. The shortest pre-imaginal development, 15.68 days was found at 25.3°C. At 27°C. and above all were killed. The threshold of development was about 2°C.

SWEETMAN H. L. DDT as a Spot Treatment for Flies. *J. Econom. Entom.* 1946 June v 39 No 3 380-81 [13 refs.]

The author observes that if one is treating buildings with DDT in order to reduce domestic flies it is sufficient to spray the particular places where flies settle or concentrate. He says that he has used "25% DDT in white or odourless kerosene [which is not possible—it is about five times more than a saturated solution]"

UNSWORTH K & GORDON R. M. The Maintenance of a Colony of *Phlebotomus papatasi* in Great Britain. *Ann Trop Med & Parasit* 1946 July v 40 No 2 219-27 3 figs. [24 refs.]

Several workers have maintained cultures of *Phlebotomus papatasi* in tropical and subtropical countries but there has been no strain maintained for long in this country notwithstanding the medical importance of the species. The classical methods essentially involved keeping the immature stages at the correct humidity and proper feeding of the adults on blood. By means of such technique five generations of *P. papatasi* have now been bred in Britain with a continually increasing population. However this method was so time-consuming that a more automatic technique has been devised. The breeding chamber in this case is inside a large block of porous cement which is soaked in water and thus ensures the correct humidity. Each day a baby rat strapped to a board is inserted to feed the adults. The larvae live in soil and in rabbit faeces at the bottom of the breeding chamber. This technique has been successful the culture being maintained with the minimum of supervision though it is as yet not possible always to ensure the production of very large numbers of flies.

KIRK R & LEWIS D. J. Taxonomy of the Ethloplan Sandflies (*Phlebotomus*). II. Keys for the Identification of the Ethloplan Species. *Ann Trop Med & Parasit* 1946 July v 40 No 2 117-29 56 figs.

The paper is without doubt valuable as a summary of the present state of knowledge. In all there are rather over forty known species from Africa south of the Sahara. The authors have excluded a number of other names on the ground of wrong identification or because they are synonyms.

The body of the paper consists of keys of adult males and females of the three subgenera, *Phlebotomus*, *Sintonius* and *Prophlebotomus*. It is assumed that one knows the subgeneric characters and can refer a specimen to one or another of these.

SWEETMAN H. L. DDT to control Cat and Dog Fleas and Dog Lice. *J. Econom. Entom.* 1946 June v 39 No. 3 417-18

BUSHLAND R. C. Insecticides applied to Forest Litter to control New Guinea Chiggers. *J Econom Entom* 1946 June, v 39 No 3 344-7

Since DDT when sprayed from the air or otherwise, was successfully used to control mosquitoes over a wide area, many attempts have been made to control other vectors of diseases in a similar manner. The experiments carried out by the author in New Guinea were made against two species of trombiculid mite *Schönastia pusilla* Womersley and *S. blestorum* Gunther they cause "scrub itch" but have not been proved to carry the rickettsia of scrub typhus. It is believed, however that scrub typhus vectors would respond in a similar way.

An area in the New Guinea forest where mites abounded, so that up to about thirty could be collected from the boots in five minutes when a man crouched on the ground was treated partly with 40 U.S. gallons [40 U.S. gallons=32 Imperial gallons and partly with 80 U.S. gallons of 5 per cent DDT in diesel oil per acre and also partly with similar quantities of diesel oil alone. Other tests were made with 5 per cent diphenylamine and 5 per cent. diphenylene both at the rate of 80 gallons per acre. The ground was also dusted with 5 per cent DDT in calcium carbonate 320 pounds being applied to an acre.

The results of all these tests were similar. There was a temporary cessation of activity but living mites were always found within three days of spraying and within about a week normal activity had been restored. The diesel oil alone was quite as successful as any of the insecticides. [It should be noted that the rate of application of DDT was several hundred times as great as has been shown to be effective against mosquitoes and yet it had no noticeable effect on the mite population.]

Kenneth Mellanby

SNYDER, F. M. & MORTON, F. A. Materials as Effective as Benzyl Benzoate for Impregnating Clothing against Chiggers. *J Econom Entom* 1946 June, v 39 No 3 385-7

Dimethyl phthalate dibutyl phthalate and benzyl benzoate, when used to impregnate garments have all been shown to be effective in preventing trombiculid mites from attaching to man. Dibutyl phthalate and benzyl benzoate have the advantage that they remain effective after the clothes have been washed [see this *Bulletin* 1946 v 43 922 923]. Extensive tests have been made at Orlando in Florida to find other substances equally or more effective and resistant to washing. Hundreds of substances have been tried, and discarded when either ineffective easily washed out or irritating to the skin. Uniforms were impregnated with the chemicals at the rate of 2 grammes per square foot (about 8 per cent of the weight of the cloth) and the wearers then sat or lay on the ground in an area abounding in mites (*Eutrombicula* spp.) Volunteers wearing untreated uniforms showed several hundred mite attachments.

The following substances were at least as effective as benzyl benzoate — benzil phenyl benzoate benzoic acid 3 5-dimethyl phenyl ester 1 2 5 6 tetrahydro-o-methyl benzoic acid, 1 2, 5 6-tetrahydro-o-methylbenzyl ester phenanthrene β -methoxydiphenyl benzoic acid, alpha methylbenzyl ester benzoic acid phenyl-ethyl ester benzoic acid, 2-chlorophenyl ester

WOMERSLEY H. A Revision of the Merotrombidinae (Acarina, Trombididae) of Australia and New Guinea. Reprinted from *Records of the South Australian Museum*. 1945 June 30 v 8, No. 2, 293-355 38 figs.

Previous work by WOMERSLEY and HEALING [see this *Bulletin* 1945 v 42, 324] has done much to elucidate the relationships of the Trombiculid mites

which cause scrub itch and which carry scrub typhus in the Austro-Malayan and Oriental regions. The present paper deals with the sub-family Microtrombididae. These mites are not themselves of medical importance but they are often confused with mites which are and their description will prevent much unnecessary field work by medical investigators. Eleven genera and forty species are described.

BERTRAM D S. An Apparatus for collecting Blood-Sucking Mites. *Ann Trop Med & Parasit* 1946 July v 40 No 2 209-14 2 figs

The mite *Liponyssus bacoti* has been successfully bred in the laboratory [see this *Bulletin* 1946 v 43 1080 and below]. One difficulty has been to isolate the mites from the sawdust and earth used as bedding for the cotton rats which are used to feed the mites. The apparatus here described consists of a sample tube to hold the infested sawdust etc. An electrically-heated coil moves slowly along the tube and this drives the mites before it into a collecting tube. The whole is mounted on a trolley and works automatically. The heated coil moves at a rate of rather less than half an inch a minute and so takes from one to two hours to traverse the three foot sample tube. The operator need only attend to the apparatus at the start and finish of the operation. Substantial numbers of mites may be collected in a typical case 113 mites, of which 60 were females were isolated. Practically all adults are evidently collected some nymphs are found but larvae (which are relatively inactive) are not. The eggs are presumably destroyed by the heat.

BERTRAM D S. UNSWORTH K & GORDON R. M. The Biology and Maintenance of *Liponyssus bacoti* Hirst 1913, and an Investigation into its Role as a Vector of *Litomosoides carinii* to Cotton Rats and White Rats, together with some Observations on the Infection in the White Rats. *Ann Trop Med & Parasit* 1946 July v 40 No 2 228-54 12 figs on 1 pl. [20 refs]

The blood-sucking mite *Liponyssus bacoti* has been shown to be a vector of filariae and also to be easily reared in the laboratory [see above]. This paper describes a similar technique for bearing the mites with full descriptions of the means used for handling individual specimens for transmission experiments.

The life-cycle of the mite is described in detail and illustrated with photographs. The life-cycle consists of the following stages: adults of both sexes the egg which develops parthenogenetically in the absence of males the six-legged larva, which moults without feeding the protonymph a blood-sucking stage the non-feeding deutonymph. The whole cycle can be completed in ten days and the mites breed so rapidly that the infestation may kill the host.

Adult mites fed on rats infected with the microfilariae of *Litomosoides carinii* often become themselves infected, though only a small proportion of the worms develop to later stages. Nymphs appear not to become infected.

The cotton rat has previously been shown to be easily infected by *Litomosoides* transmitted by *Liponyssus*. The white rat may also be infected, and the microfilariae have been found in the pleural cavity and the heart blood, though not in the peripheral circulation seventy four days after exposure. However many of the worms in white rats as opposed to cotton rats which are easily infected were dead fragmented and encapsulated and a marked cellular reaction was observed in the host. It appears probable that the white rat may therefore be unsuitable for chemotherapeutic research.

COOLEY R. A. *Notes on the Tick, Ixodes angustus* Neumann. [Research Notes.] *J. Parasitology* 1946 Apr v 32, No 2, 210.

This tick has been found to bite man. It has not been incriminated as a transmitter of human disease.

SMITH C. V. & GOUCK, H. K. *Observations on Tick Repellents.* *J. Economic Entomol.* 1948 June v 39 No. 3 374-8

The authors describe experiments in which men were exposed under natural conditions in places in the Southern United States in which ticks (generally *Amblyomma*) were abundant. The clothes were treated with a considerable number of repellent and insecticidal substances. It was found that dimethyl phthalate, benzyl benzoate, and Indalone were generally fairly effective for a period of several weeks. Pyrethrum in kerosene was effective but for a much shorter period. DDT appeared to be without effect. Untreated controls were observed in each experiment. The dose of repellent is not stated.

The work was then extended to considerable field tests: the numbers of men in each not being stated. These experiments seem to show that against the same tick, Indalone and dimethyl phthalate are the most effective of the substances tested. A high degree of protection is obtained if one treats only the edges or apertures in garments but complete protection was seldom or never obtained. The repellents are more lasting if put on garments than on skin.

BENDA, R. & FRANCHET, F. *Injections intra-médullaires osseuses.* [Injections into the Bone Marrow.] *Semaines des Hôpitaux de Paris.* 1946 Sept 7 v 22, No 33 1571-7 8 figs. [45 refs.]

The authors list a number of substances for injection which may be given by introduction through the bone-marrow. They describe the methods employed and state that this route is equivalent to the intravenous route.

REPORTS, SURVEYS AND MISCELLANEOUS PAPERS

KAUNTZE W. H. *Social Medicine in the Tropics.* *Practitioner* 1946 Aug v 157 No 928 123-30

The points made by the Chief Medical Adviser to the Secretary of State for the Colonies, in this paper are as follows. The standards of living, diet and housing of the indigenous people of most of the Colonies are poor, especially in the urban areas. Even in rural agricultural areas the crops grown, which may be suitable to local climatic conditions, are quite often not nearly so suitable to human needs and malnutrition is frequently present in the people. Housing is usually bad, water supplies are contaminated and sanitation primitive. The people, therefore, though prolific are unhealthy and consequently apathetic, and there is high mortality.

The diseases from which these people suffer are either those spread throughout the community—for instance insect borne water borne or infectious diseases—and those which are not necessarily transmissible from one person to another. In the early days of the medical services in the Colonies emphasis was naturally laid on curative medicine and of this there was more than enough to occupy the whole time of the medical staffs but as the transmission of the great tropical diseases became more clearly understood the emphasis gradually shifted towards prevention. It is the author's argument that the attitude of the medical services should more and more lean in this direction.

Prevention has been attempted in different ways—by campaigns against individual diseases (which have often failed because they were not integrated or continued) or by intensive campaigns against all diseases. For the latter a team of workers concentrates on a limited area, introduces protected water supplies conservancy systems control of disease-carrying insects good housing efficient agriculture and gives such treatment as may be necessary. Success depends on the co-operation of the people themselves, and before this can be obtained they must be educated to understand and believe in the efforts made. When the intensive work has been completed the team moves elsewhere and the permanent staff undertakes the maintenance of the new conditions. Success in these schemes depends upon the local doctor the local nurses and their assistants who are most closely in touch with the people and who can stimulate and maintain interest in the general welfare but these doctors nurses and assistants need training in social medicine and in the appreciation of the influence of total environment on health.

[Readers will be reminded of several tendencies in the development of measures to improve the health of tropical peoples, which have become apparent in recent decades. Health units have been developed (not least by the author) in Central and South Africa Mauritius and Ceylon the great undertaking of the Anchau Settlement in Nigeria has proved its worth and the Fortam service of the Belgian Congo has for long given a stimulating lead. It is surely on the lines here indicated that progress must be sought.] *Charles Wilcocks*

MANSON BAHR, P. *Tropical Medicine in the British Empire. Suggestions for the Future.* *Nature* 1946 June 29 858-60

In this paper in which Sir Philip Manson-Bahr points out that as a result of the war the number of patients returning to Britain with tropical diseases is very high, two constructive suggestions are made. The first is that as an aid to teaching there should be created a central institution at which strains of tropical parasites and their intermediate hosts should be maintained so that an abundant supply of teaching material could be available for the various schools at which tropical medicine is taught. This institution would be a miniature zoological garden with hot houses, animal houses stables and laboratories the site could be in some rural spot within reach of London. Snails, *Cyclops* mosquitoes and flies and many other animals could be bred and maintained under optimal conditions.

The second suggestion is that since there is in Britain a paucity of pathological specimens of tropical interest whereas the laboratories of the great tropical centres—Colombo Rangoon Singapore Shanghai and Hong Kong—possess ample materials an expedition should be sent to visit these and other places to arrange for proper collection and despatch of specimens to the British schools of tropical medicine.

[It would seem that these very practical suggestions should receive careful consideration if they were adopted, their value to teachers might well be enormous.] *Charles Wilcocks*

MAXSON-BAHR, P. *The Post-Graduate Teaching of Clinical Tropical Medicine.* Reprint of Chapter XVII pp. 361-73 from Albert Schweitzer Jubilee Book. 1946 London Jas. Clarke & Co. Ltd., Wardrobe Place, Carter Lane E.C.4

In this short contribution to the Albert Schweitzer Jubilee Book the author sets out some of his views on the influence of the recent war on medical teaching and on the steps which could be taken to improve the teaching of tropical medicine in Britain. He refers especially to the needs of students from abroad. His remarks on the collection of material in tropical countries are similar to those already recorded.

Charles Wilcocks.

BOYD W. S., STUBBS T. H. & WEINSTEIN P. P. *The Tropical Disease Education Program of the United States Public Health Service.* *Pub. Health Rep* Wash. 1946 May 17 v 61 No. 20 707-11

The most important diseases brought to the United States by men returning from tropical war service are thought to be malaria, amoebiasis, filariasis, hookworm infection, leishmaniasis, schistosomiasis and hydatid disease. The American Society of Tropical Medicine has therefore requested the Surgeon General of the U.S. Public Health Service to consider —

(a) The organization of several teaching teams to visit State and other laboratories for the instruction of personnel in techniques of the laboratory diagnosis of the common tropical diseases.

(b) The dissemination of appropriate articles on the diagnosis and treatment of tropical diseases through its district directors to the practicing physician by means of State and local public health and medical publications.

(c) The formation of a library of teaching films on tropical diseases to be loaned to medical societies and other appropriate organizations.

As a result a Tropical Disease Education programme has been developed in Atlanta, and plans have been made to offer intensive training in the diagnosis of parasitic diseases to technicians already employed by State and local health department laboratories. The course lasts six weeks of which the first two are devoted entirely to the microscopical diagnosis of malaria, and the remainder to the study of other parasites as they are found in clinical human material. This course is to be repeated every three months so long as it is needed, and will be flexible to meet particular needs. An extension service has also been devised, by which stained specimens are sent from time to time to 105 laboratories in 43 States, so that the accuracy of the technicians may be checked. Specimens are also sent to teaching centres. The Diagnostic and Training Centre at Atlanta now also offers a consultative diagnostic service.

A second objective of this service is to further the instruction of medical men in the subject of tropical medicine, and for this purpose it has concentrated upon the development of visual materials—photographs lantern slides and films—to be used in teaching centres and at meetings of medical societies.

Charles Wilcocks

ANDREWS J. M. *The United States Public Health Service Communicable Disease Centre.* *Pub Health Rep* Wash. 1946 Aug 16 v 61 No. 33 1203-10

This seems to be an account of the organization and programme of the Centre in Atlanta referred to in the preceding abstract though the names given to the centres are not the same. The Communicable Disease Centre has taken over the functions of the Office of Malaria Control in War Areas and deals largely with diseases common in the tropics and transmitted by insects the author

points out that very large numbers of Americans infected with these diseases are returning or have returned from military service in the tropics and that there is a constant danger of the introduction of infected persons or of non-indigenous vectors into parts of the United States in which the diseases could spread or the vectors multiply. Moreover when the need for medical men and others skilled in parasitology and tropical diseases was felt during the recent war the number available was small.

The development of the centre is summarized in three categories — (1) Training and training-aid production (2) Epidemiologic and laboratory services (3) Operational services. Training in the control of malaria, typhus plague etc. and in the diagnosis of these infections is offered to State and local health officers. It includes the usual methods and the production of articles charts exhibits lantern slides and films. The epidemiological and laboratory services provide the means for instruction and for investigation of outbreaks of disease. The operational services will deal with the control of diseases and the testing of material and equipment including insecticides. These services will be available for emergency control and will also provide demonstrations of methods in appropriate areas.

The author notes that by 1945 upwards of half a million American soldiers had contracted malaria chiefly due to *P. vivax* and that these men diffused on return over the whole country could well establish the disease in new communities. The other possible infections in returning soldiers are also considered in relation to spread within the United States.

Most of the expenditure (70-80 per cent.) of the Malaria Control in War Areas organization has been accounted for by labour. Special investigations of operational significance were carried out in association with the National Institute of Health the Tennessee Valley Authority and other organizations. These wartime operations are rapidly diminishing but it is felt that a basic organization of physicians engineers and biologists should be retained partly to avoid repetition of the situation in 1942 when there were not enough competent teams to control malaria in overseas forces, partly to deal with infections introduced into the United States and partly to combat certain endemic diseases notably murine typhus sylvatic plague and insect borne virus infections which are progressively infiltrating and entrenching themselves in new sections of the United States.

Charles W. Wilcocks

RHODESIA SOUTHERN Report of the National Health Services Inquiry Commission 1945. pp iv + 124 1946 Salisbury Rhodesian Printing and Publishing Co. Ltd.

The Commission consisted of Professor C. F. M. Saint (Chairman) and four members the terms of reference covered enquiry into the following matters —

(i) The provision of an organised National Health Service in conformity with the modern conception of Health which will ensure adequate medical, dental nursing and hospital services for all sections of the people of Southern Rhodesia.

(ii) The administrative legislative and financial measures which would be necessary in order to provide Southern Rhodesia with such a National Health Service.

It would not be possible within a short space to give even the headings of this comprehensive report and those who are interested in the subject should consult the original. The Commission have made recommendations for the development of the medical services which, if carried into effect, would exercise a profound effect on the health of all sections of the population.

They have evidently been influenced by the schemes prepared in the Union of South Africa and by the Foréani service of the Belgian Congo. There is much evidence of the need to integrate the health services with those relating to agriculture and animal husbandry.

This report is one more sign of the need felt throughout Africa, for a revision of existing organizations in relation to health. There is little doubt that in the near future that continent as a whole will be much better served than hitherto.

Charles W. Crocker,

MOTTOULE L. Quelques statistiques médicales et démographiques concernant la main-d'œuvre indigène de l'Union Minière du Haut Katanga. (Some Medical and Demographic Statistics relating to the Native Craftsmen in the Upper Katanga Mines.) 1925-1944. *Ann Soc Belge de Méd Trop* 1946 June 30 v 28 Nos 1-2, 31-5.

MANSON J M S. The Maldives Islands and their Inhabitants. *J Roy Nav Med Serv* 1946 Apr v 32 No 2 105-12 6 figs [10 refs.]

There is little available information on health conditions in the Maldives Islands and the present communication is therefore of particular interest. The islands comprise a group of coral atolls and individual islands 400 miles south west of Ceylon. The people are of Arabian, Indian and Ceylonese origin, and are Moslems. The population of the southern islands numbers 14,500 and as a rule the people are mostly concentrated in one village on each island. The houses are primitive with roofs of iron thatch or tiles, the floors are of coral sand which is removed and replaced frequently. Beside each house is at least one well, for drinking water, but there is also usually a second, for washing. Clothing is simple: the ordinary people do not wear shoes or sandals which are the prerogative of royalty. There is no caste system, but social distinctions exist: the Sultan is the ruler and his Cabinet consists of men closely related to him.

Diet consists chiefly of rice which is all imported, and of the products of the rather poor soil—coconuts, papayas, bananas, bread-fruit, sweet potatoes, yams, pumpkins, hives and mangoes—fowls (with their eggs) and fish. Toddy is made from the young shoots of coconut trees, but is consumed fresh: no alcoholic liquor is allowed. Education is slight and the people do not approve of new ideas: it is forbidden to introduce modern inventions. Modern medical attention is not available. The commonest malady is chronic ulceration of the legs, but malaria, filariasis, elephantiasis and anaemia are prevalent. Amoebiasis, bacillary dysentery, tuberculosis, bronchitis, asthma, poliomyelitis and leprosy are also mentioned.

During the war scrub typhus became of great importance. It is endemic in the Maldives Islands and caused much trouble among the British forces, who were stationed there. The papers by HAY [this *Bulletin* 1945 v 42, 109] and ZARR [ibid 111] refer to the Maldives: there were many cases of scrub typhus in men of the Royal Navy and though the case-mortality rate was not high, the morbidity rate was considerable. The larval mites concerned in transmission were probably *Trombicula deliensis*, but proof of this could not be obtained. In the indigenous people there is no evidence that scrub typhus is common, but infections are probably acquired in childhood.

The author discusses malaria, which is prevalent. (He states that the vector is *Anopheles fasciatus*. No anopheline species of that name is known to the reviewer, nor is *fasciatus* so far as can be ascertained, a synonym of any other species. COVELL (*J Malaria Inst. of India* 1944 v 5 424) notes that *Anopheles tessellatus* is the only anopheline so far recorded from the Maldives Islands, and that it is responsible for the transmission of malaria there. It breeds in shallow freshwater wells. No doubt *A. tessellatus* is the species meant.)

Charles W. Crocker.

INDEX OF AUTHORS OR SOURCES

(The bracketed abbreviations after the page numbers indicate the subjects Page numbers within brackets indicate papers not summarized.)

Am signifies	Amoebiasis and Intestinal Protozoal Infections	Leish signifies	Leishmaniasis
